form appendix is a matter of general knowledge. Enteroliths that cause intestinal obstruction may be divided into three classes: (1) true enteroliths, (2) mixed enteroliths or phytobezars and (3) intestinal concretions due to ingestion of medicaments. True intestinal stones or enteroliths present usually a small organic nucleus. They develop in the presence of stasis and in an alkaline medium (Winterstein 1923). They are usually found therefore in the large intestine and occasionally in the terminal ileum. Their occurrence in diverticula along the mesenteric border of the small intestine has been repeatedly noted. The occasional presence of enteroliths in Meckel's diverticulum is well known. Alkaline mineral salts of phosphorus, calcium or ammonium may be deposited about the central nucleus of the stone. Mixed stones are formed usually by the husks or peeling of fruits. Intestinal contents are then deposited about them in the alkaline medium of the lower intestinal canal. Following the prolonged ingestion of calcium, magnesium, bismuth and salol, intestinal stones may form. In painters and shellac workers development of such stones has been observed.

Clinical features of enteroliths that cause intestinal obstruction are not unlike those due to gallstones or other foreign bodies in the intestinal tract. Some are radiopaque and may be visible in roentgenograms.

Treatment.—The principles detailed under the caption "Intestinal Obstruction Due to Gallstones" are pertinent here. If the obstruction is incomplete suction applied to a duodenal tube will frequently permit of removal of the foreign body in an unobstructive phase. If the distention is considerable temporary exteriorization of the involved segment of the intestine is in order.

Intestinal Obstruction Due to Worms.—Infestations of *Ascaris lumbricoides* occasionally give rise to intestinal obstruction usually in children. Occasionally the symptoms have followed the institution of vermifuge therapy. Rost has isolated from the *Ascaris* a substance which exhibits a marked stimulating effect on the tonus of the intestine of the rat. The administration of vermifuge may liberate from the worm a toxic substance that precipitates a spasm of the bowel. Occasionally the presence of these worms may be demonstrated roentgenographically. If the obstruction is incomplete as is usually the case the temporary employment of duodenal suction will result in the automatic establishment of intestinal continuity. If the mass of worms persists, however, operation may be in order. Wherever possible the intestine should not be opened for the *Ascaris* exhibit an unusual tendency to work its way through the suture line. This has been reported after gastric resection and may also be observed in the experimental laboratory following enterostomy on the dog's intestine.

Intestinal Obstruction Due to Meconium in the Newborn.—Epithelial plugs adherent to mucous membrane which when unrolled give the appearance of long flat casts of the intestinal wall have been known to give rise to obstruction in the newborn (Fialto 1923).

Fecal Obstruction of the Bowel (Hirschsprung's Disease).—**Etiology.**—A somewhat frequent cause of fecal obstruction of the bowel is congenital enlargement of the colon and rectum. The first com-

plete description of this disease was given by Hirschsprung in 1866 and since then this disease has been known by his name.

Prognosis.—The risk as far as the acute obstruction is concerned is not great though if the obstruction goes unrelieved perforation of the colon may occur. Ultimate permanent relief from the condition demands correction of the underlying difficulty.

3. INTESTINAL OBSTRUCTION DUE TO COMPRESSION FROM WITHOUT

Etiology.—In such instances the mechanism usually consists of compression of the bowel at some fixed point by a tumor mass or other mechanism extrinsic to the bowel. The sites at which such obstructions frequently occur are (1) the retroperitoneal duodenum where the duodenum is crossed by the superior mesenteric artery, (2) the terminal ileum at its insertion into the cecum and (3) the pelvic colon. The bony landmarks of the pelvis account for the frequency with which an incarcerated mass in the pelvis may compress the pelvic colon and give rise to obstruction. Tumors of the mesentery or large retroperitoneal tumors which fix the intestine permit the bowel to become squeezed and occluded by a small mass which a larger mass would fail to accomplish if the bowel were mobile enough to escape. Inflammatory masses particularly when in the pelvis may obstruct the bowel by pressure. The adhesion factor of organization of fibrinous adhesive bands linking the bowel may occasionally play a not wholly minor role in the development of obstruction in such instances.

Clinical Features.—The history, physical examination and roentgen observations usually establish the diagnosis. In so-called arteromesenteric ileus there may be frequent vomiting. Aspiration of the stomach and having the patient lie prone so that the drag of the mesentery falls away from the duodenum usually afford relief. Roentgen examination with barium usually demonstrates dilatation of the duodenum up to the point where it is compressed by the superior mesenteric artery. The scout film in other types of obstruction by compression usually indicates the site of the obstruction.

Treatment.—The obstruction is usually incomplete and operation is rarely demanded for relief of the distention. An anastomosis between the retroperitoneal duodenum and the first loop of the jejunum affords adequate relief in many instances of so-called arteromesenteric ileus. Some cases of so-called arteromesenteric ileus are due to compressive developmental bands which cause narrowing of the lumen of the duodenum. In these cases it is best, as Laill (1922) has indicated, to free the bowel rather than make a new stoma. If the obstructive mechanism is inflammatory, suction applied to a duodenal tube often adequately cures the distention and under conservative management including the application of local heat to the abdomen and to the region of the groin where possible the obstructive element is satisfactorily dealt with. Occasionally operation is in order to remove the mass. Celiotomy occasionally must be performed particularly for the "plaster of Paris" indurative accompanying parametritis and cellulitis of the pelvis.

B. **INTESTINAL OBSTRUCTION DUE TO ADHESIONS AND BANDS**

Frequency—In every series of cases of intestinal obstruction, this group constitutes from 30 to 40 per cent of the cases

Etiology—There is uniform agreement that most adhesions causing intestinal obstruction develop after operation. Of 162 cases of adhesive ileus reported by Flesch-Tiebesius (1920) operation had been previously performed in 113 cases. Appendectomy for suppurative appendicitis necessitating drainage is a most frequent antecedent. Operations on the female pelvic organs rank second as a precursor of postoperative adhesions causing obstruction. It is an interesting fact that there appears to be no direct correlation between the location or presence of the adhesions and the development of intestinal obstruction. Bryant (1923) in performing 297 routine postmortem examinations with the point in mind of determining the occurrence of adhesions found that the transverse colon in both males and females was most frequently involved. Next in frequency adhesions were found around the gall bladder, duodenum, omentum, ascending colon, hepatic flexure, appendix, liver and descending colon.

Adhesions that give rise to intestinal obstruction may be of congenital origin, as the fold that binds the terminal ileum to the cecum. Adhesions may form also in consequence of external blunt trauma or following intraperitoneal hemorrhage and other inflammations of all varieties and following tumor implants in the abdomen. Adhesions after endometrial transplants in the pelvis are not infrequent. The adhesive type of tuberculous peritonitis commonly causes chronic intestinal stasis and occasionally acute intestinal occlusion.

Adhesive bands may cause obstruction by actual compression of the bowel through traction, kinking of the intestine or by effecting a volvulus or torsion of the bowel. Meckel's diverticulum may give rise to obstruction by any one of these mechanisms. Bands causing obstruction usually concern the small intestine when the large intestine is involved the flexures of the colon are usually implicated, the hepatic splenic and sigmoid flexures. Adhesive bands causing obstruction may be narrow representing mere threads or they may be broad peritoneal folds.

Intestinal obstruction through the agency of adhesions following operation may occur at any time—most frequently within the first four weeks but at any time thereafter and have been observed years later.

Pathology—Adhesive bands may give rise either to simple intestinal obstruction or to the strangulation type. The most frequent occurrence is simple occlusions of the bowel by compression, kinking or traction. Volvulus or torsion is not infrequent through the medium of abnormal bands in the peritoneal cavity. Wilms (1906) has described this variety of intestinal obstruction in considerable detail under the special caption of "Knotting of the Small Intestine."

Clinical Features—Intermittent gas pains are the patient's first complaint. If the condition occurs in the immediate postoperative

convalescence the nature of the lesion perhaps is not suspected until nausea and vomiting occur. A roentgenogram taken at that time usually shows the distended intestinal coils. The audition of loud intestinal borborygmi at the height of the pain establishes the presence of intestinal colic which together with the roentgenogram establishes a diagnosis of intestinal obstruction. If the adhesive bands merely block the continuity of the bowel, tenderness is not found. If a loop of intestine is strangulated, sanguinous fluid escapes into the peritoneal cavity giving rise to tenderness of the abdominal wall. The insertion of obstructing adhesive bands to the anterior parietal peritoneum occasionally gives point tenderness in simple obstruction. Visible peristalsis is rarely noted in acute adhesive obstruction. The roentgenogram indicates whether the obstruction is complete or incomplete.

The history of a previous operation is often significant. The story of antecedent previous attacks of intestinal colic accompanied by nausea and vomiting suggests the diagnosis. In fact, the diagnosis may frequently be made over the telephone.

Differential Diagnosis—In the immediate postoperative period especially following operation for an inflammatory process, the existence of peritonitis may suggest itself. In such a circumstance however the abdomen is silent whereas the abdomen of intestinal obstruction presents intestinal colic. Occasionally it is difficult to distinguish with accuracy between an inflammatory lesion causing simple obstruction and an adhesive mechanism occasioning torsion and strangulation of the intestine. Sometimes it is impossible to make a differential diagnosis without performing an exploratory laparotomy.

Prognosis—The outlook is essentially measured by the nature of the manner to which the intestine is obstructed. Whereas a general mortality of 40 per cent is reported, timely recognition and judicious treatment should result in a much lower percentage (Wangensteen et al 1939).

Treatment—A partial adhesive obstruction may be satisfactorily treated in many instances by suction applied to an intubated duodenal catheter. When the obstruction is complete as indicated by the absence of gas

in the colon after the administration of enemas operation is often advisable. In early instances of simple obstruction the operation of election viz locating and determining the exact nature of the obstructive mechanism may be done as well as relief of the imprisoned bowel. In late instances simple enterostomy is the operation of choice. In strangulation obstruction which is heralded at operation by the presence of hemorrhagic fluid and an infarcted segment of intestine the viability of the loop must be determined. No matter how ill the patient may be if the bowel is not viable it must be excised. In the small bowel the tendency is increasing to do primary resection followed by immediate closed (aseptic) anastomosis.

C HERNIA

1 **Intestinal Obstruction Due to External Hernia—*Etiology***—External orifices at which hernia occurs most frequently are the inguinal femoral and umbilical. These are also the hernias that most frequently give rise to intestinal obstruction and symptoms of strangulation. Less frequently strangulation may be seen in incisional epigastric, obturator lumbar sciatic and perineal hernias. In 903 operations for hernia at the Hospital for Ruptured and Crooked Bull and Coley (1907) report 24 cases of strangulation. Strangulated hernia is essentially a disease of active adult life most cases occurring between the ages of twenty and fifty although it may obtain from infancy up through old age.

In inguinal hernia the external ring constitutes the most frequent cause of strangulation. Less frequently strangulation occurs at the internal ring and occurs on all the constriction may be in the sac. Right inguinal hernia is more common than left and similarly strangulation on the right side is observed more frequently than on the left. Because of the more gradual development of direct inguinal hernia and the progressive stretching of the hernal orifice strangulation only infrequently occurs in direct hernia.

Femoral hernia ranks as one of the common causes of intestinal obstruction of the strangulating variety. Femoral hernia is much less common than inguinal still the frequency with which strangulation occurs in femoral hernia closely approximates that of the inguinal group. The rigid walls formed by Poupert's Gimbernat's and Cooper's Ligaments constitute a treacherous aperture through which a loop of bowel may protrude. In consonance with the greater incidence of femoral hernia in women strangulation also occurs more frequently in the female. The rigid fascial insertions into the linea alba at the umbilicus make for frequent strangulation of the intestine at this site. In the newborn owing to occasional lack of fusion of the abdominal walls at the umbilicus a large defect may be present into which intestine and even portions of the liver and stomach may become herniated.

Pathology—Hernial orifices through which the contents of the abdomen may protrude for the most part have hard fibrous edges which quickly compress and strangulate the intestine as it makes its way through such a channel. In consequence the bowel is quickly deprived of its blood supply and tissue necrosis develops unless the bowel is released from the compression. At operation on changes are noted in the color of the intestinal tissue depending on how long it has been entrained in the hernial orifice. The bowel is distended with fluid and gas. Usually it is empty when it makes its way into the hernial canal and when gas and fluid are driven in under the motive force of peristaltic contraction their progress is impeded by the obstruction offered at the distal end of the loop. In those instances in which considerable gas and fluid fail to find their way into the strangulated segment the effects of pressure are often manifest only at the site where the bowel is constricted. When the intestine is released from the strangulating mechanism the remainder of the tract may fail to show any effects of the constriction. Invariably however if the intestine is considerably distended the effects of increased intraluminal tension are manifest throughout the segment being most in evidence at the site of constriction.

Clinical symptoms of strangulated hernia are those of intestinal obstruction with the addition of a painful tender and often tense swelling at one of the hernial orifices. The history of the previous existence of a hernia is usually obtained occasionally, however strangulation may be the first warning of such a protrusion. A tympanic note can frequently be demonstrated over the imprisoned bowel. In the presence of considerable exudation into the sac this note may be dampened somewhat but is never dull as is the percussion note produced by incarcerated omentum. In femoral hernia particularly impingement of a portion of the intestinal wall by the tendinous margin of the femoral canal is likely to occur without actually establishing the presence of a block to the continuity of the intestinal current (Richter's hernia). A similar occurrence may take place at the inguinal epigastric umbilical and obturator apertures though less frequently than in the femoral canal. Occasionally a strangulated hernia will only have omentum in its sac even though the symptoms of vomiting suggesting intestinal occlusion may be present. Pain down the inner side of the thigh as far as the knee (Howship Romberg sign) corresponding to the sensory distribution of the obturator nerve in the presence of symptoms of intestinal obstruction suggests strangulation in an obturator hernia but it is only inter-

quently diagnosed prior to operation Vaginal or rectal examination may disclose a tender mass above the inferior ramus of the cecum Perhaps nowhere is the value of early treatment of intestinal obstruction better illustrated than in strangulated hernia Bower (1927) found that the average length of time elapsing between the onset of symptoms and operation for strangulated hernia was thirty one hours whereas for cases of intestinal obstruction within the abdomen the time was seventy six and six tenths hours the latter time being greater by 177 per cent

Prognosis—Braun and Wortmann (1924) state that 1795 patients with strangulated hernia were seen at the Friedrichshain Hospital in Berlin during the years between 1903 and 1922 In this group death occurred in 280 cases (15.6 per cent) In 1509 of the entire group no gangrene was present Of these patients 136 died (a mortality of 9 per cent) Of 286 patients with gangrene 144 died (a mortality of 50.9 per cent)

Treatment for all cases of strangulated hernia is immediate operation with release of the intestine from the strangulating mechanism The incision should generally be a little more generous than is ordinarily employed to permit of adequate exposure After interruption of the strangulating mechanism the hernial sac should be opened and the condition of the bowel ascertained The return of normal luster to the bowel and pulsation to the vessels indicates that the bowel is viable In instances of doubtful viability primary resection should be done Surgical procedures on the intestine if necessary are occasionally best done through a separate incision after the strangulation has been reduced

Reduction of the strangulated hernia by taxis is of doubtful value unless the patient is seen within a short time of the strangulation taxis is better not attempted In a comprehensive report on the value of spinal anesthesia in ileus Duval (1927) refers to several cases in which perforations were found in the bowel after reduction of a strangulated hernia by taxis

2 Intestinal Obstruction Due to Internal Hernia.—Internal hernia occurs relatively infrequently During an eighteen year period in which 1795 patients with ex-

ternal hernia were operated on at the Friedrichshain Hospital in Berlin only 21 patients with internal hernia presenting features of obstruction were treated during the same interval of time Strangulation may be caused by (1) diaphragmatic hernia (2) hernia into the foramen of Winslow (3) hernia of the paraduodenal fossae (4) hernia into a persistent hole in the mesentery (5) hernia into the intersigmoid fossa and (6) paracecal hernias Some of these may not be true hernias in the restricted sense since they have no peritoneal covering

D VOLVULUS

Volvulus or torsion of the bowel occurs usually in the sigmoid flexure A long flexure in which the limbs of the loop are closely approximated predisposes to its occurrence It is also significant that in most instances in which volvulus of the sigmoid flexure obtains an unusually large bowel or pseudo-megacolon with a long mesentery is present Less frequently volvulus involves the cecum and terminal ileum and less commonly the small intestine stomach or transverse colon The rarity with which volvulus of the transverse colon is seen bespeaks the importance in the development of torsion of the narrow attachment of the mesentery The transverse colon despite its extreme range of motion escapes frequent twisting because its points of fixation at the hepatic and splenic flexures are so far removed from one another

In most statistical studies of intestinal obstruction volvulus constitutes about 10 per cent of the total number of cases In Russia and Serbia volvulus appears to occur frequently In 215 cases of intestinal obstruction reported by Ierlma (1925) from a Russian surgical clinic 111 or more than half were cases of volvulus Wortmann grouped the reports of a number of Serbian authors and found that in 393 cases of intestinal obstruction volvulus was present 127 times All writers stress the greater length of the intestine and the significance of the vegetable diet of the Russian people as a contributing factor to the frequent occurrence of volvulus According to Braun and Wortmann C. Roschmann found abnormally long flexures of the pelvic colon in only 4.2 per cent of the postmortem examinations made in German whereas Samson in a similar material in Russia found 20 per cent Long periods of fasting followed by indulgence in overeating is a common practice among the Russian peasants and is believed to play a causative role Volvulus occurs three or four times more frequently in men than in women The greatest incidence of the disease occurs in middle and advanced years

Volvulus of the cecum and small intestine has as its essential cause an abnormally mobile segment of small intestine with inadequate fixation of its mesentery. In such cases the cecum usually possesses a continuation of the mesentery of the terminal ileum. Other cases present evidence of incomplete rotation of the right colon. Overfilling and gaseous distention appear to be contributing factors.

Pathology—Torsion of from 180 to 360 degrees is usual but in cecal torsion involving the small intestine a twist of from 50 to 70 degrees may be seen. When there is a broad mesenteric attachment a twist of more than 180 degrees is unusual. Mesenteric cysts occasionally give rise to torsion of the intestine and volvulus of the small intestine may occur when a gall stone blocks the lumen.

Circulatory changes vary with the degree of vas-

cclusion. Frequently such patients have had previous attacks of pain from which recovery has been spontaneous.

Visible peristalsis may frequently be observed in torsion of the sigmoid flexure less commonly in volvulus of the cecum and small intestine. In the presence of marked vascular occlusion constitutional symptoms of severe degree may be present, quickening of the pulse with hurried respiration and abdominal tenderness and rigidity are frequently noted. If the obstruction remains unrelied symptoms of severe circulatory shock due to loss of blood into the strangu-

Fig. 366—Plömpert at necropsy in a case of volvulus of the sigmoid flexure. Note the enormous distention of the segment which has under one torsion. Its wall is thick and discolored because of the hemorrhagic infarction. The proximal colon is somewhat distended but the small intestine is not at all distended because of the action of the ileocolic sphincter. (Courtesy of Dr. N. F. L. Skene.)

cular occlusion are regularly present. Free peritoneal fluid, gangrene and even perforation of the twisted segment may be seen. The strangulated loop presents evidence of distention with gas and fluid. The segment proximal to the site of torsion is also dilated. The direction of the twist in torsion of the small intestine is usually clockwise though counter-clockwise twists are observed. In torsion of the cecum the direction of the twist is about evenly divided. In the sigmoid flexure the clockwise twist appears to be more frequent.

Clinical Features—The distention is often extreme (Fig. 566). The distended coil corresponding to the twisted sigmoid flexure or cecum can frequently be seen over the abdomen and may be palpated as an elastic tumor exhibiting marked tympany on per-

cussion. Frequently such patients have had previous attacks of pain from which recovery has been spontaneous. The roentgenogram indicates the location of the obstructed intestinal coils.

Differential Diagnosis—Mesenteric thrombosis, acute pancreatitis, peritonitis and strangulation of an internal hernia may mimic torsion of the lower very closely. The establishment of the presence of intestinal occlusion indicates that some type of intestinal occlusion is present and the peritoneal irritation incident to the escape of blood into the peritoneal cavity indicates the necessity for operative intervention. Stenosing carcinoma of the sigmoid flexure may be confused with volvulus of the sigmoid flexure.

Spastic colitis with gaseous distention of the colon may occasionally simulate the picture of torsion

Prognosis—The mortality in intestinal torsion is about 50 per cent. In those cases requiring excision because of gangrene, the mortality has been about 80 per cent.

Treatment—Mild torsion sometimes can be relieved by the administration of a barium enema and detorsion of the colon can be observed under the fluoroscope. In most instances, however, operation is indicated. If the operation is performed soon after the symptoms develop, simple untwisting of the strangulated segment alone may suffice. If the strangulated loop is considerably distended, puncture and aspiration of its content may facilitate detorsion with less risk of spillage. If the vascular occlusion has been of long standing and is severe, circulatory changes in the intestine frequently necessitate excision of the segment. In the sigmoid flexure under such circumstances exteriorization after the Mikulicz method may be indicated. In volvulus of the small intestine, if the strangulated segment is long, a primary anastomosis is usually the operation of choice, but if the devitalized segment is short and in the lower ileum, exteriorization is safer.

It is well known that following detorsion, volvulus of the sigmoid flexure often recurs. The intestine may be fixed by means of plication, colopexy or lateral anastomosis, but usually excision after the Mikulicz method or primary resection is the operation of choice for recurrent torsion of the sigmoid flexure.

E. INTUSSUSCEPTION

The frequency with which intussusception occurs varies widely in different countries. In England, Denmark and Australia it constitutes one of the most frequent varieties of obstruction observed. In the United States it appears to be definitely less frequent. About 75 per cent of all instances of the disease are seen in children under two years of age, more than half of the cases occur during the first year of life, and most of these are observed between the fourth and ninth months of life. The remaining 25 per cent occur throughout the years, being more frequent in early childhood than later.

The disease usually affects healthy infants. It occurs three times as frequently in the male. In intestinal invaginations observed in infancy an etiological agent is usually not apparent. In adults on the contrary a tumor of the bowel, Meckel's diverticulum or ulcer

affords satisfactory evidence of an etiological role in about 70 per cent of instances. Intussusception occurs most frequently at the ileocecal juncture where vigorous peristalsis is countered by antiperistalsis in the cecum. This occurrence may have some significance as to its genesis. A large number of the cases occur at the time of weaning and it is believed that this change in the diet leads to intestinal spasm.

Pathology—Cases of intussusception may be classified as representing either large or small intestinal invaginations. Intussusception of the large intestine may be ileocecal in which the head of the cecum forms the apex of the invaginated bowel, or a pure colic invagination. In the small intestine there may be ileocolic invagination in which the lower ileum prolapses through the ileocecal valve, or a pure enteric invagination.

Fig. 567—Types of intussusception.*

Occasionally a loop of the jejunum may telescope through a gastroyejunostomy stoma into the stomach. In the presence of a pyloric tumor the stomach has been known to telescope into a dilated duodenum. Intussusception of the appendix into the colon has occurred several times.

The usual intussusception consists of three cylinders, viz. internal and returning layers constituting the intussusceptum. The outer tube is known as the intussusciens or ensheathing layer. A double intussusception presents 5 cylinders and as many as 7 may be present in a compound intussusception.

Most intussusceptions occur in the neighborhood of the termination of the ileum. Ileocecal intussusceptions appear to be most frequent, accounting for about 60 per cent of instances. The ileocolic variety occurs in about 30 per cent of cases and the remainder are fairly evenly divided among enteric, colic, multiple and double intussusceptions. Intussusception is almost invariably of the descending variety but ascending varieties do occur.

The obstruction in intussusception is afforded by the active contraction of the sheath, especially at the neck; actual block of the lumen does not occur. The continuity of the intestinal lumen between oral and distal segments remains intact and in chronic intussusception

*Wangensteen: Intestinal Obstructions. Charles C. Thomas Publisher.

in which the changes in the intestinal wall are not so marked the intestinal current is preserved. The greatest alteration in the bowel in acute intussusception occurs in the intussusceptum. The walls of the invaginated segment rapidly become edematous stiff and engorged with blood. Extravasation of blood into the lumen occurs. Acute intussusceptions tend to become irreducible rapidly owing to the changes in the intussusceptum. Ulceration, gangrene and perforation of the invaginated bowel may develop in irreducible intussusception. The bowel above the obstruction is usually dilated and presents some evidence of congestion. In chronic invagination the bowel may undergo considerable hypertrophy.

Clinical Features—There are four cardinal symptoms of intussusception: (1) periodic attacks of pain, (2) vomiting, (3) passage of mucus and blood by rectum and (4) presence of a palpable tumor. Pain and vomiting are practically constant in occurrence. The sudden onset of painful seizures in a previously healthy infant is characteristic of intussusception. After a little the infant seemingly recovers, but in a little while he cries as if in pain. Alternating periods of pain and relief occur again and again.

Clubbe (1921) found that in 97 per cent of his cases blood was passed by rectum in from two to ten hours following the onset of the seizure. [Blood may be demonstrated by digital examination of the rectum.—Ed.] Enteric invaginations may not present blood in the stool. In pure colic intussusception blood is constantly in the stool early. An abdominal tumor is felt in about 60 per cent of instances. The pure enteric invaginations are notably difficult to feel. Clubbe states that only twice in 253 operations which he has performed for intussusception did he open the abdomen without having previously palpated the tumor. In ileocecal invagination the tumor is usually felt as a banana-shaped area to the right of the umbilicus stretching up toward the right costal margin; it may however be present on the left side of the abdomen as is usual in the more mobile ileocolic invaginations which may occasionally be palpated by digital examination of the rectum. Imparting to the examining finger the consistency of the uterine cervix. Enteric invaginations are always short and very small mobile tumors lying in the neighborhood of the umbilicus. In colic invaginations the tumor is usually found on the left side of the umbilicus in line with the descending colon.

The tumor of intussusception stiffens with the painful seizures and relaxes when the peristaltic rush is over. With the succeeding attacks of colic it advances its position and increases in size. The administration of 1 Gm. or more of chloral hydrate to infants in whom intussusception is suspected relaxes the infant and helps to establish the presence of a tumor. The abdominal wall may become moderately rigid during the painful seizure owing to the intestinal contraction. Distention is a rather late sign. It should be mentioned that intussusception is the one variety of strangulation obstruction in which tenderness and rigidity of the abdominal wall are frequently absent. This is readily explained in that the ensheathing cylinder which contains the strangulated intussusception is normal and that the greater exudation occurs inside this normal ensheathing cylinder. Occasionally however slight blood-tinged fluid may be present in the peritoneal cavity giving rise to tenderness.

Differential Diagnosis—Enterocolitis, appendicitis, mesenteric thrombosis, rectal prolapse and Henoch's purpura occasionally must be differentiated. Usually the findings in typical instances of intussusception are so characteristic that the disease is readily identified. In atypical instances however some of these may be difficult to differentiate. In intussusception blood is not mixed with the stools as it is in enterocolitis. In the latter both fever and constitutional disturbance are marked from the onset of the illness. Appendicitis rarely occurs in children under two years of age and blood in the stool is infrequent. Mesenteric thrombosis and arterial embolism are essentially diseases of advanced age and a tumor is rare. In rectal prolapse intestinal obstruction does not exist and the examining finger may readily detect the nature of the protruding bowel. Intussusception has been known to occur during the course of Henoch's purpura. Patients with purpura are usually older than those with typical intussusception and other evidences of purpura such as rash, pains in the joints, hemarthrosis or hematuria are frequently manifest. The constitutional symptoms usually overshadow the abdominal features—abdominal pain, vomiting, diarrhea, melenæ—which

may be present. The blood in the stool is intimately mixed with the feces. A palpable tumor may develop as a result of hemorrhage into the intestine and cause an actual obstruction.

Prognosis—In the best available series of cases reported the mortality has been as low as 3 or 4 per cent (Clubbe 1901 Taylor, 1925 Hipsley 1926 1937). The more usual mortality is from 10 to 20 per cent. In late cases necessitating resection the risk is always great particularly in the case of infants.

Treatment—Early reduction of the invagination by operation is preferable. No matter where the tumor presents in intussusceptions of infancy a short right rectus incision should be made a little below the umbilicus. The invaginated intestine is pushed backward from below, only the most gentle traction being exerted on the invaginated bowel toward the completion of the reduction if necessary. The initial portion of the reduction is accomplished within the abdomen guided only by the sense of touch. The reduction of the apex of the intussusception is the most difficult part of the procedure and should always be carried out under direct vision.

When the interval following the onset of the disease has been fairly short reduction of the intussusception is accomplished with relative ease. When strangulation has been present for some time reduction may be impossible. In such instances the bowel must be dealt with in some other manner. A lateral anastomosis between segments of the bowel proximal and distal to the intussusception is usually safer than excision of the irreducible segment. Infants in whom this disease usually occurs notably tolerate excision of the devitalized bowel poorly. Clubbe states in his monograph that only 19 successful resections for gangrene or irreducible invaginations in children under one year have been reported. If reduction of the intussusception is accomplished and it is found that the intestine is not viable in adults it is wiser to do a two stage resection in the first the devitalized intestine is exteriorized in the second the continuity is reestablished by suture. Occasionally following the reduction of intussusception the patient has a high fever for a few days an in-

dication of impaired viability of the bowel wall. McVasson and Clarence Dennis did a successful primary resection for a gangrenous irreducible intussusception in a two month old infant. A carefully performed closed resection should lower the mortality in late cases. In the main however the greater salvage of life will attend surgical reduction of the invaginated bowel before resection becomes necessary.

Non Operative Reduction—Hirschsprung (1905) gained worldwide renown for his successful reduction of intussusception by the non operative method. In early intussusception the invaginated intestine may be simply forced back by the administration of a barium enema under gravity pressure of 3 feet. In infants in whom invagination is likely to occur in the neighborhood of the cecum complete filling after the intussusception has been pushed back indicates that the reduction has probably been complete. However in children past the time of life when intussusception is frequently observed the method should not be employed because of the frequency with which compound intussusception occurs.

Recurrent Intussusception—Acute intussusception rarely occurs. Clubbe states that he has twice had to reoperate for recurrent invagination. In the instances of recurrence reported in the literature the cause has usually been found to be a small tumor within the bowel. In an edematous bowel following reduction of the invagination small tumors within the intestinal wall may be easily overlooked.

Chronic Intussusception—Inversion of the bowel does not uniformly eventuate in acute obstruction and strangulation of the telescoped segments. Congestion and edema are the factors that produce obstruction in strangulation. Occasionally the blood supply of the bowel is not vitiated obstruction is incomplete or absent resulting in chronic intussusception. It occurs most frequently in adults and often in the presence of a tumor or Meckel's diverticulum which serves as the entering wedge for the development of the invagination. In 129 such cases collected by Goodhall (1910) from the literature the condition had existed for more than six months in 32 patients and for more than one year in 11.

Symptoms of chronic intussusception are usually atypical. In the majority of instances however the onset is abrupt as in acute intussusception.

F ERRORS (OTHER THAN CONGENITAL STENOSIS) IN DEVELOPMENT OF THE INTESTINE GIVING RISE TO INTestinal OBSTRUCTION

(See Section on Congenital Anomalies of the Intestine)

II INTESTINAL OBSTRUCTION DUE TO NERVOUS IMBALANCE

A INHIBITION (PARALYTIC) ILEUS

Etiology—This type of obstruction is most often seen in peritonitis. Its occurrence in mild grades following intra-abdominal operations of practically every sort is well known. Incident to each operative intervention in the peritoneal cavity a moderate parietic condition of the bowel obtains in which distention and difficulty in expelling gas are present. As the paresis begins to diminish dilated loops contract down on their gaseous and fluid content and gas pains are felt. Reflex inhibition ileus is observed following strangulation of the omentum in renal attacks not uncommonly and less frequently in gallbladder colic following torsion of an ovarian cyst or strangulation of the spermatic cord. Reflex dilatation of the intestine with markedly impaired motor power may obtain. Fractured ribs, injuries of the spinal column, blunt trauma to the abdomen, embolism and thrombosis of the mesenteric vessels, retroperitoneal infection and hemorrhage as well as infectious fevers such as meningitis, pneumonia and typhoid fever may give rise to a severe grade of meteorism. Following the ingestion of raw beans or oats inhibitive ileus has been known to develop.

Pathology—The term paralytic ileus is badly chosen for the intestinal wall is not paralyzed; on the contrary its activity appears to be inhibited by an overactive sympathetic nervous system. After the influence of the sympathetics has been shunted out by blocking of the splanchnic nerves or by spinal anesthesia the parietic intestine of paralytic ileus can be made to contract. The

entire intestine is usually dilated in inhibitive ileus. Occasionally collections of fluid and gas concern only certain segments of the bowel. The intestinal wall is often thinned out and it is frequently somewhat dusky in appearance because of the slight venostasis occasioned by the dilatation of the bowel and the pressure on the mesenteric veins returning from over the surface of the bowel. Perforation and gangrene however rarely occur despite enormous distention.

Clinical Features—Extreme meteorism dominates the picture and may be great enough to embarrass the respiration. The patient does not complain of colicky pain as does the patient with mechanical obstruction. On auscultation the abdomen is relatively silent, only feeble noises being heard, usually no gurgling or splashing sounds are audible. Tenderness over the abdomen is usually noted, very little or no pain may be complained of. Despite the obviously dangerous condition of the patient he frequently has no conception of the gravity of his illness and euphoria is commonly observed. A scout film of the abdomen shows gaseous distention usually of the entire bowel.

Prognosis—The outlook depends largely on the cause. In peritonitis the outlook is always poor for the patient still must conquer the infection despite subsidence of the distention. Inhibitive (paralytic) ileus of reflex origin usually responds well to treatment.

Treatment of paralytic ileus presents two extreme difficulties: (1) to cope successfully with the cause and (2) to treat an inactive bowel. In inhibition ileus occasioned by retroperitoneal collections of exudate or following torsion of an ovary or testis correction of the underlying process usually brings about an amelioration of the distention. Hot stupes to the abdomen, atropine, pituitary extract, pilocarpine, physostigmine and ephedrine have all been advocated for the treatment of distention observed during the course of inhibitive ileus. Enemas may give temporary relief and may cause the evacuation of some gas but are usually of no great value. Enterostomy has been extolled by a number of authors but the experience of most surgeons is that enterostomy rarely

succeeds in emptying many loops of bowel. Spinal anesthesia sometimes gives temporary relief. Intravenous injections of hypertonic saline solution (0.16 to 0.93 Gm per kilo of body weight) frequently bring about vigorous intestinal contraction. On the whole, however, suction applied to an intubing duodenal tube is found to be more successful. The Miller Abbott type of duodenal tube is of particular value in cases of distention of this type. Nevertheless when the distention has become established occasionally suction proves of little value. In instances in which the development of inhibitive ileus is anticipated improved results may be obtained by the early institution of suction siphonage by means of a nasal catheter before distention has developed.

B SPASTIC ILEUS (DYNAMIC OBSTRUCTION)

Etiology—In this condition spastic contraction of a segment of the intestine obtains in contrast to its relaxation which is observed in inhibitive ileus. The late J. B. Murphy's (1896) initial description of the condition concerned a patient with lead colic in whom adequate cause for such unusual intestinal contractions was apparent. Most instances however concern the colon. Trauma, neurasthenia and hysteria and intrinsic factors operating from within the bowel such as foreign bodies, worms, ulcers or irritating substances have been observed to give rise to the condition. Spastic ileus has been known to occur in renal colic and in infectious fevers. A gallstone occasionally causes obstruction when its diameter is such that it could not mechanically obstruct the lumen in such instances the spastic element has been assumed to play a role. The actual mechanism by which this variety of obstruction occurs is not well understood. Occasionally patients are seen with a mixture of the inhibitive and spastic types of nervous imbalance.

Pathology—The involved segment is usually contracted and its wall thickened. The collapsed segment may be short or long; ringlike contractions are not infrequent. The bowel above the spastic area dilates and exhibits gaseous and fluid accumulations. No perforations have been noted in fatal cases.

Clinical Features—The picture of this type of obstruction simulates closely that of mechanical obstruction. In patients who have been previously operated on, confusion with adhesive ileus is likely to occur. In the experience of the writer, adhesive ileus almost invariably concerns the small intestine, whereas in spastic ileus the colon is most frequently distended. Many of these patients are definitely neurotic, and in a

non-obstructive phase the nature of their complaint is usually recognized.

Prognosis—With proper recognition and treatment the outlook, as far as the acute attack is concerned, is good. Recurrence, however, is not infrequent.

Treatment—If the ailment can be correctly identified, the non-operative course is usually the wiser. Temporary employment of suction siphonage by means of a nasal catheter together with tidal irrigation and suction applied to an intubing rectal tube usually results in abatement of symptoms.

III VASCULAR OBSTRUCTION

A INTESTINAL OBSTRUCTION DUE TO MESAENTERIC THROMBOSIS AND EMBOLISM

Etiology—Tranter (1913) collected in monograph form the reports of 360 cases of mesenteric thrombosis and embolism. Arterial occlusion was found to contribute 60 per cent of the total thrombosis of the mesenteric vessels, the remaining 40 per cent in a few smaller arteries venous thrombosis has been observed to occur more frequently than embolism of the mesenteric arteries. The superior mesenteric artery is more frequently concerned in embolism than is the inferior, partially because of its earlier exit from the aorta but largely because of its more direct continuation from the abdominal aorta. Embolism of the inferior mesenteric artery may obtain and infarction of the bowel may fail to occur significant of the free anastomosis which occurs between the end vessels of the systemic arteries and the inferior mesenteric branches. Vegetations on the valves on the left side of the heart are the usual etiologic agents in embolism of the mesenteric arteries. Embolism is more frequent than thrombosis of the artery. Mesenteric venous thrombosis is usually associated with infection in abdominal organs that are tributary to the portal vein. Appendicitis, pelvic infections and strangulation of an external hernia are frequent precursors of the condition. Thrombosis or embolism of the mesenteric vessels rarely affects children, adults between the ages of thirty and seventy are most frequently attacked.

Pathology—Distention of the involved segment with accumulation of bloody fluid in the peritoneal cavity as well as within the segment is the rule. Demarcation of the involved intestine from the normal is usually sharp though in some instances the margins of healthy and diseased intestine are poorly defined. When obliteration of the mesenteric artery occurs slowly intestinal infarction may not result. Chiene (1868) has placed on record the fatal case in a woman aged sixty-five. Autopsy was performed in the Anatomical Laboratories at Edinburgh and it was found that the abdominal aorta was completely occluded by an aneurysm that extended as far down as the bifurcation. The branches of the mesenteric arteries were filled by injection through the superior hemorrhoidal artery which was fully as large as the femoral artery.

Clinical Features—It is an interesting fact that in many cases of mesenteric thrombosis there is a fairly mild course more than a week elapsing frequently before the existence of a serious lesion is suspected. Only a few patients apparently exhibit prominently the phenomena of mechanical obstruction. The usual manifestations of this disease are the sudden onset of severe abdominal pain, vomiting and diarrhea. Stools and vomitus occasionally contain blood. Shock may be present. Distention of the abdomen is progressive though not extreme. Abdominal tumors have been palpated in about 5 per cent of cases. If arterial occlusion is present the disease tends to be more acute than when due to venous obstruction. Visible peristalsis is rarely observed. Infarction of a portion of the intestine is frequently complicated by peritonitis and its sequelae. Knowledge of the previous existence of a probable source for an embolus or adequate cause of mesenteric venous thrombosis should be present before the preoperative diagnosis of vascular occlusion can be entertained.

Prognosis—Of necessity the outlook is exceedingly poor. Nevertheless in a number of cases recovery has followed successful excision of the devitalized portion of the intestine.

Treatment—Early operation and excision of the involved segment is indicated. There are a number of reports of cases in the literature in which the abdomen has been opened and the entire small intestine found to be exsanguinated yet the patient has recovered without further operative procedure.

Excision followed by primary anastomosis is the operation of choice when it is feasible because of the length of intestine usually concerned. Exteriorization should be reserved for those cases in which the length of the devitalized segment is not excessive.

Excision of one third of the small intestine in a child is usually tolerated without untoward effect. Infants and children do not tolerate extensive resection as well as adults. In a number of cases in which the resected portion of the small intestine exceeded 6 feet in length, Moynihan (1906) found that whereas in half the patients peritonitis well many subsequently died of a paralytic condition. The most extensive successful resection on record is that of Jerrault (1909) who excised 19 feet (569 cm.) of the small intestine for gangrene

caused by embolism of the superior mesenteric artery. This patient was subsequently operated on by Jerrault for intestinal obstruction due to the so-called time 10 feet (303 cm.) of small intestine. A patient operated on by Doerfler appears to have survived with a remaining portion of small intestine so short that Doerfler was prompted to ask whether man may live without the small intestine. He resected 18 feet 8 inches (569 cm.) of the intestine for volvulus of the entire small bowels thirty hours standing. Below the duodenojejunal junction there remained 12 cm. and 20 cm. above cecum. Six and a half years later when Doerfler has reported the patient was in good health and ate of food only at regular mealtimes and ate in enormous amounts. His bowels moved normally each day some time immediately following the operation. Ever the patient was distressed by gas and by movements every four to six at that time he it necessary to eat something every few hours.

ANOMALIES, INJURIES AND FOREIGN BODIES OF THE COLON; DIVERTICULITIS; FISTULA, AND ULCERATIVE COLITIS

MEGACOLON; CONGENITAL IDIOPATHIC DILATATION OF THE COLON, HIRSCHSPRUNG'S DISEASE (1886)

The classification of megacolon includes the primary or idiopathic megacolon (Hirschsprung's disease), in which an etiologic factor cannot be found, and the secondary or acquired megacolon, in which demonstrable or questionable etiologic factors are present.

Etiology.—Except in the cases in which definite anatomical obstruction is demonstrable in the bowel the cause of megacolon is unknown. The most important hypotheses relative to the etiology are based on mechanical, inflammatory, hypernutritive congenital, neuropathic and other causes. The inflammatory theory may be discarded as untenable, there appears to be only one proponent of the theory of hypernutrition, the theory of congenital origin though not explaining the ultimate cause, is supported by several facts, although there may not as yet be any anatomic evidence for the neuropathic theory, in recent years a gradual tendency has been noted toward its general acceptance, as evidenced by the favorable response to sympathetic ramisection and ramisection.

Idiopathic megacolon is most common in infancy or early childhood. The symptoms are present from birth or early life. In a few cases symptoms do not manifest themselves until adult life, and rarely not until advanced age. More males than females are affected, the proportion being 35:1. A familial tendency is present, and a considerable number of cases have been observed in mentally defective persons, other congenital defects being frequently associated.

Pathology.—The morbid anatomy of the bowel is enlargement of the affected portion usually with hypertrophy of the walls and occasionally with elongation. The sigmoid flexure is the region most commonly affected, and the entire large intestine, exclusive of the rectum, is the next most common. The sigmoid flexure, according to Finney, is involved in the process either alone

or with other portions of the colon in 80 per cent of the cases.

Symptomatology.—The two cardinal symptoms are obstinate constipation and distention of the abdomen. These symptoms appear in typical cases during the first days or weeks of life and persist with brief periods of remission throughout life. In some cases pronounced symptoms do not appear until later in childhood or in adult life. The most striking feature is the extraordinary infrequency of bowel movements in the absence of the features of acute obstruction: the patient not defecating perhaps for a period of three or four weeks. Bowel movements are generally induced with great difficulty, large doses of drastic cathartics may be taken without effect. Stools are often large and inspissated, and the odor is often save. At intervals there may be diarrhea or vomiting. Abdominal distention, which may be present at birth to such degree as to interfere with delivery, is usually noted within the first few days or weeks of life. It is caused by distention of the colon with feces and gas and varies indirectly with the activity of the bowels. It may be uniform and general or it may be localized corresponding to the position or content of the affected portion of the bowel. Secondary symptoms (often associated) include a wide costal angle, thin abdominal wall, distasis recti hernia, distention of the superficial abdominal vessels, displacement of the thoracic viscera, dyspnea, cardiac embarrassment, audible borborygmus, visible sluggish peristalsis, edema of the extremities and impaired nutrition.

Diagnosis.—The diagnosis of megacolon may be made on a history of unusually obstinate constipation and abdominal distention in a patient apparently in good health. It may be confirmed by fluoroscopic examination with the use of an opaque enema. Megacolon must be distinguished from acute intestinal obstruction, tuberculous peritonitis, ovarian cyst and rickets.

Prognosis.—The prognosis is uncertain. In infants malnutrition and acute infections are the chief complications. In mild cases acute toxic or obstructive symptoms may supervene and cause death. Perforation of the bowel and death from pulmonary embolism have been reported.

Treatment—While the results of medical treatment for megacolon are not good most patients can be carried along without operation. If the disease is limited to the left colon resection of the left half of the transverse colon, splenic flexure, descending colon and sigmoid can be carried out by a Mikulicz type of resection thus fixing the joined barrel to the abdominal wall. This is followed by subsequent closure of the colostomy as a second stage. Operations employing plication or fixation of the colon without resection have been unsatisfactory. The emergency relief of severe obstruction by means of colostomy may be necessary. Lumbar sympathectomy with denervation of the inferior mesenteric artery and removal of the presacral nerve offers some chance of improvement or relief but has been followed by recurrences in some cases. (See the section on the Autonomic Nervous System.) Anastomosis of the ileum to the rectosigmoid with colectomy has yielded the best results of all operative methods.

VOLVULUS OF THE COLON

Volvulus is an obstruction of the intestine due to the twisting of the bowel on its axis. According to Vaughan more than half of the cases of volvulus occur at the sigmoid flexure; fewer at the cecum and fewest in the small intestine. Volvulus of the sigmoid flexure is a fairly usual condition in eastern Europe and is associated with adult life. The average age is forty-five years. It is more common in males than females (ratio of 4 to 1) although between the first and twentieth year the disease occurs to approximately equal extent in the two sexes. It is suggested that the explanation for this may be found in the lesser capacity of the abdominal cavity and the firmness of the abdominal coverings rendering it much more difficult for spontaneous reposition to take place in men. Strong and muscular men are

most frequently the victims of this disease. In women because of a wider pelvis and relaxation of the abdominal muscles as a result of frequent pregnancies there is more room in the abdominal cavity and thus greater possibility of spontaneous reposition.

The length of the flexure and the narrowness of the sigmoid mesocolon are emphasized as important factors in the development of the condition. It having been definitely established that a long flexure is a predisposing factor of great importance.

The most common predisposing cause of volvulus is the presence of structural changes mostly bands or adhesions either of congenital origin or formed by previous peritonitis. Volvulus has also been reported as due to old scar formation and chronic mesenteritis. Former operations with resulting bands and adhesions, mesenteric cysts, habitual constipation and chronic intestinal stasis with traction on the mesentery also predispose to this condition. Another cause is thought to be nonrotation of the common mesentery and large and small intestine during embryologic development. It has also been suggested that volvulus is often due to disordered peristaltic action. A high percentage of volvulus in patients with intestinal obstruction is reported in predominantly vegetarian races, the bulky diet probably resulting in intestinal atony or chronic distention thus contributing to twisting of the bowel. (For symptoms, diagnosis and treatment of volvulus see section on Intestinal Obstruction.)

INJURIES AND FOREIGN BODIES IN THE COLON AND RECTUM

Etiology.—The conformations of the rectum and sigmoid flexure render them peculiarly liable to the arrest and retention of foreign bodies which can reach these cavities (1) by being swallowed and passed through the intestinal canal; (2) by their development in the upper bowel and passage through it to the colon, sigmoid and rectum; (3) by introduction through the anus; and (4) by traveling from a neighboring organ through an ulcerated opening in the separating structures. All kinds of objects have been found in the colon particularly in the rectum. The rectal objects are not caught more often in the angulations of

the sigmoid valves of the rectum or sphincter muscles is that they are covered with fecal matter and thus pass without causing injury.

Several factors anatomical physiologic and pathologic contribute to the lodgment of foreign bodies in the pelvic bowel. The pouches or sacculi of the colon disappear as soon as the bowel enters the pelvis and the lumen of the intestine is encroached on by the rectal valves which retard the free movement of the fecal bolus. At this level the lumen further decreases and the mucous membrane is thrown into numerous longitudinal folds which terminate near the anus in the crypts of Morgagni where small bodies are frequently caught. The sphincters also completely close the lower anal canal.

Articles of every conceivable size shape and composition have been swallowed and passed safely through the intestinal tract producing no symptoms. The patient usually knows that he has swallowed some object although this may not be so in children or the insane. When large bodies are swallowed the patient is aware of the fact and usually seeks medical advice immediately. The body if comparatively smooth and of such size as to be swallowed without difficulty may be expected to pass through the intestinal canal at least as far as the sigmoid flexure or the rectum. The length of time required for passage to the rectum is very indefinite. Fruit seeds, coins, button pins and false teeth frequently pass through the digestive tract to the sigmoid or rectum where they may be caught.

Fecal concretions may develop in all the portions of the intestine where the movement of the fecal current is retarded at the cecum, the hepatic, splenic and sigmoid flexures and in the ampulla of the rectum.

Foreign bodies are sometimes introduced intentionally through the anus into the rectum for relief of certain symptoms, to excite sexual passion for purposes of concealment or by accident. The patient does not seek a physician until he is compelled to do so because of the great pain and suffering which result.

Instances in which foreign bodies have gained entrance to the rectum from adjacent organs are extremely rare. It is unusual for them to be introduced into the rec-

tum by simple accidents such as a fall on a pointed stick or on a fence post which may break off and remain within.

Symptomatology.—The symptoms are subjective and objective and vary considerably according to the location of the foreign body and the extent of the damage. The patient usually presents symptoms suggestive of common rectal ailments such as constipation, diarrhea, hemorrhage or immediately following stool passage of mucus, tenesmus and pain. If the foreign body has been swallowed or introduced into the rectum legitimately, the patient gives a frank history and a correct diagnosis is easily made. The pain depends on the shape of the object. A round smooth body causes much less suffering than an irregular one with ragged edges or sharp points. If the mucous membrane of the rectum is penetrated torn or ulcerated the pain is more or less constant particularly if the body is lodged in the lower rectum. If the object is large and has smooth rounded surfaces the pain may not be acute but rather of a dull heavy aching character increased on movement. Spasm of the sphincter and levator ani muscles is often present. Constipation and sometimes obstruction may occur. Genitourinary complications may be so marked as to cause suspicion that these organs are the seat of the disturbance. Dysuria, anuria, cystitis and pains referred to the testicles, scrotum and along the crural nerves are all frequent symptoms. These are probably the result of pressure on the urinary tract by the foreign body or are due to reflex action. If a foreign body has been lodged in the rectum for some time there may be considerable constitutional reaction. If the object has been introduced through the anus there may be some injury.

Diagnosis.—The diagnosis is in some cases quite difficult to determine. It may be made by digital examination seeing the object through a proctoscope or by means of the fluoroscope or of roentgenograms. Careful digital exploration of the rectum is advised routinely.

Prognosis.—In the majority of cases a foreign body in the rectum is removed successfully. However it may not always be successfully removed and death may result from peritonitis, shock or hemorrhage.

Treatment—Treatment depends to a great extent on the location and nature of the object. If found low down in the anus or in the rectum and not too large it can usually be extracted from below. As foreign bodies are usually introduced into the rectum with the small end first and the sphincter is thus gradually dilated until the body slips from the hand and the sphincter closes behind it the removal is generally more difficult than the introduction because the large end must be grasped and dragged down first. The spasm of the sphincter consequent on the traumatism increases the difficulty of withdrawal. The object may be grasped with forceps and removed. Pressure or manipulation may cause it to slip further into the sigmoid flexure and if it is sharp it may perforate the intestine and cause peritonitis. First the bladder should be emptied. It is usually necessary to anesthetize the patient and dilate the sphincter before any attempt at removal is made. The parts should be thoroughly irrigated so as to remove as far as possible any surface contamination that might predispose to infection. The field should be thoroughly anointed by injecting oil into the rectum and the finger should be lubricated to facilitate slipping the object through the constricted area. It is better to cover sharp or jagged edges with gauze.

When a foreign body is lodged so high in the rectum or sigmoid that it cannot be extracted through the anus there is no recourse other than laparotomy. The mortality from this method of relief is high.

DISEASES OF THE APPENDICES EPIDIDICAT

Appendices epiploicæ are defined as localized pedunculated overgrowths of subserous fat directly continuous with the fat in the layers of the mesentery. They are formed by a reduplication of the peritoneum which enmeshes a variable amount of fatty tissue between its layers and consist of small processes or pouches which are confined to the large intestine none appearing on the rectum.

The number of appendices epiploicæ pres-

ent may vary widely an adult usually possessing about 100. While arranged along the whole course of the large intestine they are most numerous in the transverse and pelvic colon (the cecum as well as the vermiform appendix sometimes giving origin to them) but there are none in the rectum. The appendices are arranged in two rows one in relation to the anterior muscular band the other to the posterior band.

The lesions incident to the appendices epiploicæ may be divided into the following groups: 1. Mechanical interference with the blood supply by direct pressure or torsion. (a) Within the abdominal cavity or in a hernial sac. (b) formation of foreign bodies within the peritoneal cavity or in a hernial sac as a result of interference with the blood supply, (c) torsion associated with and secondary to other inflammatory lesions of the abdominal cavity. 2. Infection of the appendices epiploicæ. These are incident to or associated with interference with the blood supply or to lesions of the corresponding segment of intestinal wall (diverticulitis). 3. Adhesions of the appendices epiploicæ causing intestinal obstruction.

Foreign bodies in the peritoneal cavity the end result of torsion of the appendices epiploicæ give no definite symptomatology unless infected then the symptom and signs of peritonitis will predominate. They may cause vague abdominal complaints simulating those of gallbladder or other disease. Sudden torsion of the appendices with or without infection results in sudden sharp abdominal pain not necessarily limited to the seat of torsion. The pain may be referred to the right side of the abdomen when the torsion actually exists in an appendage of the sigmoid flexure. Vomiting, tenderness and rigidity (in short the picture of an acute surgical condition which mistaken for acute appendicitis or diverticulitis or diverticulitis) supervene. The treatment is surgical.

DIVERTICULOSIS AND DIVERTICULITIS

Definition.—When one or more pouches are found in the large intestine the term *diverticulosis* is applied. Diverticula may

occur throughout the gastrointestinal tract but are most common in the sigmoid colon. When inflammation occurs in one of the pouches the term *diverticulitis* is applied. Diverticuli of the large intestine are found in 3 per cent of the population and in 5 per cent of persons over forty years of age. They are usually multiple and may possess all of the coats of the large intestine (true diverticula) or have only mucosal and serosal coats (false diverticula). If the opening of the sac into the intestine is large there will rarely be associated symptoms. Inflammation may follow inability to empty the diverticulum of its contents. Diverticulitis is more likely to occur in false diverticula because of the lack of a muscular coat for emptying it as well as in those with a small opening into the colon.

Etiology.—Most diverticula have a congenital origin. They may later increase in size and number although there is probably an inherent weakness in the wall with constipation being the most important developing factor. They are most apt to occur in sedentary and obese individuals.

Symptoms.—Many patients with diverticulosis have no symptoms or have symptoms that are so minimal that medical advice is not sought. Vague abdominal distress, chronic indigestion, constipation and shifting abdominal pain may be present. On the other hand, diverticulitis is always accompanied by symptoms of varying severity. Abdominal pain usually occurring in the left lower quadrant or over the immediate site of the diverticulitis, fever, leukocytosis and abdominal tenderness are the rule. A mass is usually present. Mild and intermittent bleeding of the bowel occurs in 20 per cent of cases. Obstructive symptoms are common.

Treatment.—All patients with diverticulosis accompanied by symptoms should be treated by dietary and medical means. Like wise all cases of acute diverticulitis should be treated by rest and diet. The use of sulfonamides or penicillin is hardly justified. Operative treatment should be limited to those with recurrent attacks, to those with abscess formation or to those with obstructive symptoms. Operative treatment for possible abscess should be delayed until fluctuation can be felt, since in most cases the

abscess will perforate into the bowel lumen and spontaneous cure result. When obstruction persists a proximal colostomy should be performed preferably at some distance proximal to the infection. For the typical diverticulitis of the sigmoid with obstruction a double-barreled colostomy of the transverse colon of the Mikulicz type is the procedure of choice. With diversion of the fecal stream subsidence of the inflammatory process will usually result in an adequate lumen of the bowel and this type of colostomy can readily be closed extraperitoneally. If symptoms persist in spite of proximal colostomy, resection of the area involved should be carried out with end-to-end anastomosis before closure of the proximal colostomy. No resection for diverticulitis should be done as a one-stage procedure because of the high mortality which results from peritonitis. The presence of a sigmoidal vesical fistula demands proximal colostomy followed in six to twelve months by resection with closure of the bladder opening.

In many cases it will be difficult to exclude carcinoma coincidental with diverticulitis. The differential diagnosis can usually be established by proctoscopic examination or by the barium enema or double contrast air enema. If after these examinations doubt still exists as to the presence of an accompanying malignant growth, resection should be carried out.

The mortality for operations for diverticulitis in the past has varied from 20 to 50 per cent but this can be materially lowered if proximal colostomy, two-stage operations and delayed operative treatment are carried out.

GRANULOMATOUS DISEASES OF THE COLON

Granulomas of the colon are a localized inflammatory process and may be of specific or non-specific etiology. Since reduc-

tion in the incidence of tuberculosis of the intestine they are rarely encountered

Etiology—The following conditions are included in this group (1) tuberculosis (2) non specific cicatrizing regional colitis (3) gumma (4) actinomycosis histomoncosis and hydatid disease and (5) lymphogranuloma

Tuberculosis—Until recent years tuberculosis of the cecum was more frequently encountered. In most cases the process was limited to the right colon at times including the first half of the transverse colon. The ingestion of the tubercle bacilli in the presence of pulmonary tuberculosis or from the milk of infected cattle could usually be shown to be the cause. Intestinal tuberculosis of a mild type could usually be controlled medically. A short circuiting operation joining the ileum to the transverse colon when obstruction is present usually gives little relief. Resection of the entire area of involvement including as much mesentery and glands as possible is the procedure of choice.

Non Specific Cicatrizing Regional Colitis—This condition in the colon is similar to that occurring in other portions of the gastrointestinal tract notably the distal ileum. The symptoms are the same as for obstructing carcinoma of the intestine and the condition cannot be differentiated by a barium enema or by an air contrast enema. Resection should be performed in all cases and usually the diagnosis is first considered on examination of the resected specimen. The results of resection are good.

Lymphogranuloma—Lymphogranuloma usually is confined to the rectum and obstructive symptoms are present. The condition is differentiated from other granulomatous lesions by means of the Frei test. Multiple sinuses and fistulas are common complications. The obstructive symptoms can be relieved by proximal colostomy in the sigmoid colon but this does not do away with the rectal symptoms including tenesmus and discharge as well as the secondary effects of the infection. Abdominoperineal resection has yielded the best results in these cases.

COLONIC FISTULAS

A colonic fistula is an abnormal channel or communication between the colon and a hollow viscus (internal fistula) or between the colon and the surface of the body (external fistula). Fistulas may be congenital or acquired (pathologic traumatic or post operative). Most colonic fistulas are post operative following drainage of an abscess or direct injury to the colon during operation or caused by infection or leakage at the suture line following resection. A spontaneous fistula as a result of an inflammatory process may occur from ulcerative colitis, diverticulitis, jejunal ulceration following gastroenterostomy, regional enteritis or colitis, tuberculosis, actinomycosis or lymphogranuloma.

Pathology—Whether internal or external the fistula is rarely completely lined with mucosa or skin. It has a thick wall with diffuse inflammation and is usually adherent to surrounding structures. A spontaneous fistula shows the characteristic findings of the disease causing it.

Symptoms—The most characteristic symptom is the discharge of fecal material with pus and blood. A patient with an internal fistula in the proximal colon may have few bowel symptoms. A patient with a fistula in the distal colon and rectum has the bowel symptoms that are present with any organic large bowel lesion. In cases of multiple fistulas and those associated with intraperitoneal infection, intermittent fever, weight loss, inanition and anemia are found.

Diagnosis—An external fistula is at once evident. Its extent can be demonstrated in roentgenographic films after injection of an opaque medium such as barium diodist or lipiodol. An internal fistula can usually be shown with the barium enema or by gastrointestinal series. A fistula of a specific type can be differentiated by the examination of the discharge or by biopsy of the tract.

Treatment—Operation should be delayed for three to six months until time elapses for possible spontaneous healing. Furthermore, this interval permits subsidence of the inflammation about the tract so that operative removal is facilitated. Complete excision of the fistula is the procedure of choice and can be accomplished by entering the abdomen at a site removed from the

fistula in order to identify its extent. The incision can then enclose the fistula, followed by excision and closure of the bowel, but in many cases resection is required. At times a two stage operation is advisable, with diversion of the fecal stream by sidetracking anastomosis or by means of a proximal stoma followed by later closure or excision of the fistula.

ULCERATIVE COLITIS

Definition.—Ulcerative colitis is a non-specific inflammatory lesion of the colon and

leading to its onset. The enterococcus of *Bergen*, bacillary dysentery, amebic dysentery, a neurogenic factor leading to spasms of the colon, an allergic factor and dietary deficiency may make the colon susceptible to a mixed infection.

Pathology.—In 90 per cent of the cases the disease begins in the sigmoid or rectum as a mucosal infection, as evidenced by hyperemia of the mucosa followed by minute hemorrhagic ulcerations which may be confluent. The ulcerations usually begin under the longitudinal band and may be confluent, leading to destruction of the greater portion of the mucosa. Infection spreads through the submucosa to involve all coats of the

Fig 568.—Chronic ulcerative colitis—"lead pipe" colon

rectum, occasionally involving the distal ileum. Other inflammations of the colon of a similar diffuse type due to some specific cause, such as bacillary dysentery, amebic dysentery and the granulomatous lesions, should not be included under this diagnosis.

Etiology.—A number of possible causes of this disease have been proposed, with considerable evidence to support them by their proponents, yet none can be considered as a specific causative agent. Until more acceptable evidence has been presented, this must be considered to be a non-specific disease with several possible causative factors, either singly or in combination,

including the muscular and serosal coats. The disease spreads by continuity both along the mucosal surface and through the lymphatics. The muscular coat becomes markedly thickened and the serosa injected. If no remission occurs, the disease continues proximally to involve all of the colon and, in 20 per cent of the cases, the distal ileum. At times the disease is segmental in character, involving only portions of the colon, such as part of the transverse or right colon, or remains confined to the lower sigmoid and rectum. In the course of healing, there is marked contraction, so that in advanced cases the lumen of the bowel may be re-

Fig 569—Chronic ulcerative colitis with marked fibrosis and polypoid change

Fig 570—Acute diverticulitis with obstruction. Differentiation from malignant growth by air contrast enema.

duced more than half. In some cases the colon becomes a rigid tube the so called lead pipe colon incapable of contraction or other function. When healing occurs in the milder cases the mucosa may remain red, denuded and granular even in the presence of complete remission. The cicatricial stage of the disease may be accompanied by abscesses, fistula or sinus into other portions of the intestine, bladder, vagina or perineum. Anorectal disease is a common manifestation. Pseudopolyps produced by islands of mucosa between ulcerations is common in the late stages of the disease.

Symptoms—The symptoms of ulcerative colitis can be grouped into general and local symptoms. The general symptoms are those of any infectious process. Fever, malaise, weakness, prostration, loss of weight, dehydration and anemia are conspicuous. The local symptoms are all bowel symptoms. Diarrhea, tenesmus, passage of blood, mucus and pus, generalized abdominal and rectal pain focus attention on the large intestine as the site of the lesion.

Diagnosis—The disease is confirmed in the presence of the aforementioned symptoms on proctoscopic examination. The diffuse character of the mucosal involvement, bleeding from the mucosa on manipulation of the proctoscope or by swabbing cannot be readily confused with that of other inflammatory diseases of the lower large intestine. The Craig complement fixation test for amebic dysentery, the stained smear and cultures for bacillary dysentery and examination of the stool for *Endamoeba histolytica* and the tubercle bacillus exclude the various possible causes. The proctoscopic examination may be negative in 10 per cent of the cases when the upper colon is involved in a segmental form. The characteristic appearance of a malignant growth plus biopsy confirmation makes it possible to exclude carcinoma which must be considered as a possible diagnosis in all cases. Malignant growth on the basis of a pre-existing ulcerative colitis is rare, occurring in less than 1 per cent. The barium enema is used to determine the extent of the involvement as well as the stage of the disease. In the presence of ulcerative colitis the lumen of the bowel is decreased, the haustral markings are decreased or absent, motility is decreased and there is

foreshortening of the bowel. In advanced cases in which ulcerative colitis has existed for a long time the length of the colon may be diminished by half.

Treatment—Medical treatment should first be tried in all cases of ulcerative colitis both in its acute and in its chronic form. Medical treatment is unsatisfactory because of poor response or recurrence of the disease in approximately 40 per cent of the cases. In 15 per cent of these cases the patient can be continued on medical treatment with some incapacity while 25 per cent will require surgical treatment because of complications of the disease not amenable to medical treatment.

Indications for surgical intervention are as follows: (1) intractability on medical treatment with incapacity persisting for three months or more each year, (2) obstruction of the colon because of cicatricial change, (3) subacute perforation, abscesses, sinuses or fistulas, (4) persisting hemorrhage, (5) infectious arthritis, (6) polypoid change, (7) carcinomatous change.

Operative Procedures—In the past surgical treatment has been unsatisfactory either because the wrong operative procedure was employed or because surgical treatment was accepted too late. Appendicectomy, cecostomy and ileostomy have been tried and have proved to be useless. Ileostomy or colectomy, either partial or complete, is the operative procedure of choice.

Ileostomy should be performed in any acute case where response is not satisfactory within seven days under medical management. It should be employed in all cases of the seven groups previously listed as indications for operation. The ileostomy may necessarily be permanent if sufficient destruction has taken place in the colon. If clinical remission occurs in the presence of ileostomy, the colon can be left in. If healing occurs with clinical relief of symptoms and if a satisfactory proctoscopic appearance of the lower bowel and distensibility are present as shown by a barium enema, the ileostomy may be resected and intestinal continuity restored. This is done in approximately 10 per cent of all ileostomy cases. If symptoms persist in spite of ileostomy, then either partial or total colectomy should be performed. Partial colectomy is employed

when the patient has the segmental distribution of the disease and total colectomy, including removal of the distal ileum the entire colon and rectum is performed in all other cases.

The lives of many patients with ulcerative colitis have been lost because ileostomy would not be accepted by the patient or the physician. There may be considerable difficulty in the care of an ileostomy and this has led to reticence in accepting it. Every patient must wear an ileostomy bag since the ileal discharge may be liquid or semi-solid. The ileostomy should project sufficiently above the skin level so that the discharge passes immediately into the bag without contact with the skin. Many preparations such as aluminum or bronze powder, kaolin, fuller's earth, ointments of all types, compound tincture of benzoin and various dyes have been used to protect the skin but these are unnecessary since skin excoriation can be prevented by a properly performed ileostomy and a properly fitted ileostomy bag. Bags of the Davol type with a small aperture, the Traveller or the Koenig-Rutzen are the most satisfactory. The latter can best be fitted three to six months after the performance of ileostomy and is cemented in the skin fitting the ileostomy perfectly; it is changed but twice in twenty-four hours.

Prognosis.—A patient with an ileostomy even after total colectomy can resume his normal activity that was pursued before the onset of the disease. The mortality of ileostomy varies between 0 and 25 per cent depending on the stage of the disease when it is performed. Partial and total colectomy can be carried out with a mortality under 10 per cent for all stages. There is no difficulty in maintaining a satisfactory state of nutrition on a normal diet.

BENIGN POLYPOID TUMORS OF THE LARGE BOWEL

The different types of benign polypoid tumors of the large bowel are (1) adenoma, (2) papilloma or villous tumor, (3) multiple polyposis and (4) inflammatory polypus. The clinical incidence of these tumors is not great but in about 20 per cent of persons over twenty years of age adenomas are found in the colon at autopsy (Lewy).

ADENOMA OF THE RECTUM AND COLON

Pathology.—This type of epithelial tumor is the most common benign neoplasm that is found in the gastrointestinal tract. Adenomas occur most frequently in the colon and rectum but are not found in the esophagus, stomach and small bowel. In the small bowel a pedunculated adenoma is a

Fig. 371.—Photograph of a multiple pedunculated adenoma of the rectum from a man aged twenty-five.*

frequent cause of intussusception in adults. In the colon adenomas are found in all portions at all ages from childhood to old age. While clinically they are most often found as single tumors at autopsy, if one is found further search will often reveal several others. Adenomas may vary from the size of a grain of wheat to that of a hen's egg. As regards the attachment to the bowel the tumor may be sessile or pedunculated. The larger the adenoma the more frequent is a

* *Lewy's Practice of Surgery*, W. F. Prior Co. Publ. Co.

pedicle formed by traction of the tumor on the mucosa. The pedicle consists of normal mucosa and may become several inches in length thus allowing the tumor a considerable range of excursion in the lumen of the bowel.

Histologically the appearance of these adenomas varies from hyperplasia of the normal intestinal mucosa to marked increase of the glandular elements of the mucosa as evidenced by branching tubules, multiple cell layers and deeply staining nuclei. In the pedunculated adenomas of children the tumor is covered with rather normal intestinal epithelium and the body of the tumor contains a myxomatous connective tissue in which are the cystic enlargements of the

bleeding is slight but noticeable. In childhood adenoma of the rectum is probably the most frequent source of recurrent bleeding from the large bowel. When the adenoma is in the left half of the colon the blood is usually on the outside of the stool because of the solid character of the stool in this location. Conversely when the bleeding tumor is in the transverse colon or right half of the colon the blood is inside of the hard stool or intimately mixed with it. Obviously the brighter and more fluid the blood is the lower in the colon is the bleeding lesion.

In children in whom a pedunculated adenoma is most often found in the rectum the pedicle may become long enough for the tumor to protrude from the anus at stool. It

Fig. 57a.—Histomicrograph of a pedunculated adenoma of the sigmoid colon in an adult.

glandular structures of the epithelium. This wide variation in the histologic structure of these tumors as well as their rather frequent occurrence in the region of carcinomas of the colon and rectum has definitely raised the question of their relationship to cancer.

Symptomatology and Diagnosis.—Clinically considered adenomas of the colon and rectum may be wholly without symptoms. This is particularly true if they are flat and small. However if they become pedunculated and are subjected to more trauma, bleeding occurs and this is the most common symptom noticed by the patient. On occasion the bleeding may be copious and from 4 to 6 ounces may be lost. Usually the

has a characteristic red and slightly lobulated appearance. When adenoma is suspected but no protrusion has occurred digital examination of the rectum may allow the tumor to be palpated and the finger may hook around the pedicle and prolapse the tumor through the anus.

Proctoscopic examination should always be carried out if adenoma of the rectum or colon is suspected if the tumor can be seen the site and character of its attachment to the colon its freedom of movement and the question of ulceration can be determined. It must be remembered that a pedunculated adenoma of the colon can prolapse into the rectum if the pedicle is long also with an air inflation proctoscope a pedunculated

adenoma of the rectum may be blown upward into the colon and therefore not observed.

The site of the adenoma in the large bowel above the rectum can be determined only by fluoroscopic examination of the colon. It may be possible to push an air bubble filling defect up and down in the bowel for a few inches because of the freedom permitted by the pedunculated attachment of the tumor. This air bubble defect must always be present in the same place on repeated examination if a reasonably safe diagnosis is made. It should be emphasized that this filling defect is not due to indentation or malformation of the regular outline of the bowel but is a defect resembling an air bubble within the lumen of the bowel. In some cases it is impossible to find a filling defect and the diagnosis can be established only by exploratory laparotomy after other possible sources of bleeding from the stomach and bowels have been ruled out. It is recognized that bleeding from a carcinoma of the small bowel or Meckel's diverticulum is extremely difficult to diagnosis. The following brief case report will serve as an illustration.

A man aged fifty three who in times past had been treated medically for a duodenal ulcer and had been free of symptoms for several years noticed blood intermittently in the stool. The blood was fluid and sometimes red but often clotted and was on the outside of the stools. Repeated proctoscopic and fluoroscopic examinations failed to reveal the source of the bleeding. As gross bleeding of relatively fresh blood continued an exploratory laparotomy was performed and a pedunculated adenoma about 2 cm. in diameter with a long pedicle of normal mucosa, was palpated in the sigmoid loop. With rubber blade clamps on the bowel above and below the tumor the bowel was opened along the longitudinal muscle band the polyp delivered, the pedicle ligated, the tumor removed and the bowel closed in layers. No other lesions were found.

Treatment—The treatment of an adenoma in the rectum is simple when the pedunculated tumor can be propped through the anus. The pedicle is ligated and the tumor removed. If the tumor is higher but can be seen through a proctoscope it can be grasped with a slender tenaculum and rotated so that the pedicle is visible. The pedicle can then be fulgurated and the adenoma removed. When the adenoma is flat or it is impossible to reach the pedicle, the tumor itself can be fulgurated and re-

moved in one or more stages. The disadvantage of the last procedure is that the tumor cannot be adequately studied histologically. These patients should be examined again after six weeks and the former site of the tumor inspected.

PAPILLOMA, VILLOUS TUMOR

Pathology—A papilloma is a soft sponge-like arborescent tumor which is rather infrequently found in the colon and rectum. Only 30 such tumors have come to the author's service. They occur practically always in adults. The usual symptoms are frequent passage of bloody mucus from the bowel or sudden rather copious hemorrhage. A hemorrhage of a pint or more of blood has been the first symptom in some cases. If present in the rectum the tumor can be palpated as a soft indefinite mass without induration at its point of attachment to the bowel. It can be seen through the proctoscope where it appears as a lobulated arborescent tumor having a flat attachment to the bowel and not infrequently completely surrounding the bowel or attached to an area several inches in length. If the tumor is in the colon it may give a filling defect very much like that of carcinoma and with symptoms of bleeding cannot be clinically distinguished from carcinoma. When the tumor is palpated through the intestinal wall however it feels soft and there is no change of the usual external appearance of the intestinal wall. In some cases the tumor cannot be palpated at all in the splenic flexure though a definite filling defect is seen in the roentgenogram. Not all papillomas are seen when they have attained such size and in the early stage of their growth they may be slender branching stalks. These tumors differ from carcinomas in that they are not infiltrated or ulcerated and histologically they do not invade the basement membrane or muscular mucosa of the intestinal wall. The cells covering the branching stalks are higher than those of the normal mucosa have many more goblet cells and have deeper staining nuclei. It is concerning this type of tumor and the flat adenomas with cellular changes that the question arises as to whether they are pre-malignant growths. If it is maintained that infiltrating destructive growth is the principal sign of cancer, then multiple-layered

epithelium polymorphous nuclei or branching lobules of epithelium give only a suspicion but no proof that a malignant growth is present. Practically speaking the clinician and the pathologist should have common

Fig 53—Gross specimen of a papilloma of the rectum in an adult

knowledge about any single case under discussion the appearance of the tumor and its lack or presence of induration or ulceration

Fig 54—Air bubble filling the defect from a polyp at A

as well as the histologic picture must be fully considered. It is of great importance to submit the whole tumor for histologic examination as the invasion of cells through the basement membrane which is characteristic of cancer can be determined only by an examination of the site of attachment of the

tumor. The examination of small pieces of tumor from the surface of the growth may be misleading and fail entirely to indicate the character of the tumor.

Treatment—It is obvious that papillomas of the rectum or colon should by choice be entirely removed for histologic examination. In the rectum this may necessitate splitting the rectum posteriorly after removal of the coccyx so that a complete local removal of the tumor can be accomplished after which the defect may be sutured and the rectum closed by layer stitches. When the papilloma is in the colon a resection of the colon is necessary in order to remove the tumor.

MULTIPLE POLYPOSIS

In cases of multiple polyposis a rather rare familial condition the entire colon including the rectum is studded with multiple adenomas and small papillomas. All sizes and shapes are present including the flat or

Fig 55—Colon showing multiple polyposis. There were also three separate carcinomas.

pedunculated varieties. The condition has been seen in childhood but is most frequent in young adults. The symptoms are those of frequent passages of blood and mucus, passage of small pieces of tumor tissue rapidly developing anemia and cachexia. Proctoscopically the rectum is seen to be studded

Fig 376—Giant section through the bowel showing multiple polyps. The tumors are adenomas and papillomas. At A there is a carcinoma.

with adenomas and fluoroscopically the colon has a characteristic mottled appearance owing to the numerous small filling defects. Carcinoma frequently develops and is often multiple. In the colon shown in the illustration there were three separate carcinomas. It is generally agreed that preliminary ileostomy followed by graded removal of the colon and rectum is advisable if the condition of the patient will permit it. Too often it happens that severe anemia and cachexia or the rapid and extensive development of carcinoma precludes radical treatment.

INFLAMMATORY POLYPS OF THE COLON AND RECTUM

In the course of a protracted ulceration of the colon from amebic dysentery or ulcerative colitis, small islands of mucosa between the ulcers hypertrophy, become fibrotic and have the gross appearance of adenomas. These growths may reach the size of a walnut and give symptoms of bleeding or partial obstruction of the bowel. One patient who had had a longstanding ulcerative colitis was found to have several polyps of this type in the rectum and sigmoid which had been present for ten years. In another patient with ulcerative colitis a small polyp developed and when it was removed through the proctoscope it was found to be malignant in structure. In some instances stalk-like papillomas and flat adenomas develop in a rectum which is the seat of a chronic inflammation. In one such patient a colostomy was performed because of severe and uncontrollable bleeding from a group of such papillomas which appeared benign on histologic examination. After the

colostomy had been established the tumors in the rectum disappeared. The meaning of this evidence is not entirely clear but indicates that inflammation may produce lesions which resemble in detail the structures which are called adenomas or papillomas and which are regarded as tumor formation.

CARCINOMA OF THE COLON

Carcinoma is the most frequently encountered tumor of the colon. The apparent increase in its incidence together with cancer in general is very probably due to two factors: first, that a larger number of cancers are recognized than formerly because of modern means of diagnosis; and second, that cancer is chiefly a disease of middle and later life. The average life of man which was formerly forty-two years has been increased during the twentieth century to fifty-eight years so that a greater number of people are reaching the so-called cancer age. In other words, the supposed frequency of the disease is a credit to improved methods of diagnosis and prolongation of the lifetime of man.

Of the entire intestinal tract, less than 1 per cent of carcinomas invade the small bowel. The two mobile terminal segments of the colon, the cecum and the sigmoid, are most frequently involved. In a large series of cases which the authors have studied, approximately 36 per cent of the growths were located in the colon and 64 per cent in the rectum and rectosigmoid.

Etiology.—Carcinoma of the colon may occur at any age, and although it is usually found in the fifth and sixth decades, it is not uncommon to find it in patients between the ages of twenty and thirty. Males are more frequently affected than females, in the proportion of about 2 to 1.

The origin of carcinoma of the colon, like carcinoma elsewhere, remains obscure, although some progress has been made in respect to its predisposing and contributing causes. Bardenheuer and later Quenu and Landel were the first to bring forward his

theory in which the association of the polyps with carcinoma was fairly proved to be more than accidental. In the series of 50 cases of polyposis reviewed by Doering, there were 37 deaths, of which 31 were from carcinoma.

Pathology.—Carcinomas of the colon may be conveniently classified, according to their gross and microscopic anatomy, as (1) soft medullary adenocarcinoma, (2) scirrhous or fibrocarcinoma and (3) mucoid or colloid adenocarcinoma. The different types are responsible for the marked varia-

A

B

Fig. 577—A, Resected specimen of the splenic flexure of the colon. Note the dilatation and hypertrophy proximal to the annular carcinoma. B, Resected specimen of a colloid carcinoma of the ascending colon; a bulky ulcerating growth.

tologic evidence of the malignant transformation of adenomatous cells. Hauser, Kraske, Verse and more recently FitzGibbon and Rankin, and many others have since reported numerous instances of carcinomatous changes in colonic polyps. Proof is lacking that all carcinomas of the large intestine originate in polyps, but there is considerable evidence to support the belief that most of them arise in just such a manner. FitzGibbon and Rankin reported 13 cases in which these changes were definitely demonstrated, and at least 140 cases have been re-

ported in symptoms as well as the roentgenologic evidence. In the right half of the colon, large, bulky ulcerating lesions, often covered with stubby protuberances like granulation tissue (Fig. 577, A), occur usually on the lateral wall of the colon and produce ulcerating surfaces for absorption but do not tend to produce obstruction, because of (1) the liquid nature of the fecal current at this point, (2) the lack of tendency to encircle the bowel, the lumen of which is greater here than elsewhere in its course, and (3) the likelihood that the growth will go on to

penetration perforation or the formation of abscess. On the other hand in the distal segment of the large bowel carcinoma usually originates close to the mesenteric border and spreads laterally diminishing the size of the lumen and consequently producing chronic subacute and even acute obstruction (Fig 577 B). One may however occasionally encounter a polypoid lesion.

Multiple primary carcinomas of the colon may occur and although they are not often recognized the possibility of such multiplicity of lesions should be kept in mind since it has a significant bearing on prognosis. Birge and Rankin have reported 16 such conditions in the large intestine. Volvulus and intussusception occur quite frequently as complications of carcinoma of the colon.

Approximately 5 per cent of carcinomas of the colon and rectum are of the mucoid type. Rankin and Chumley reported 158 operative cases of which number 85 (53.8 per cent) occurred in the colon and 73 (46.2 per cent) in the rectum. This histogenesis of mucoid carcinoma is uncertain although many pathologists regard it as a degenerative process. This type of malignant lesion although slow growing is in the end more malignant from the standpoint of ultimate cure than the other types of carcinoma of the colon. Its tendency to recurrence once the regional lymphatic vessels are invaded is most marked.

Eventually regardless of pathologic type ulceration and secondary infection develop. The infection is at first localized but may terminate in spreading suppuration, fistulous tracts or peritonitis. Obstructing carcinomas may produce dilatation and hypertrophy of the intestine above the growth (Fig 577 B). Instead of hypertrophy the intestinal wall may be markedly attenuated above the growth and the mucosa may present a moth eaten appearance because of innumerable small ulcers.

Metastasis in carcinoma of the colon as a rule occurs later than carcinoma of any other portion of the gastrointestinal tract. The lymphatic vessels gauge the extensiveness of the lesion and their invasion influences the prognosis considerably. However distant metastasis even to the liver has been noted although the lymph nodes were not involved. The lymphatic structures of

the cecum and appendix according to Poirier and Cuneo are more extensively developed than those of the other segments of the large intestine yet metastasis from the cecum is among the slowest of any segment of the large bowel. It would seem therefore that rich lymphatic supply is a defensive mechanism and favorable to prognosis because it holds in check the invading malignant growth.

It is highly important to subject nodes and tissues to microscopic examination during operation in order to ascertain if one is working in an invaded area. A detailed consideration of lymphatic metastasis may be found in the section on Carcinoma of the Rectum.

Symptoms.—To record in sequence the chain of symptoms caused by carcinoma of the large bowel is difficult if not impossible particularly if it is desired to emphasize merely the earlier manifestations of the disease.

The reasons for this are that developmentally and on all anatomical and physiologically the right and left halves of the bowel differ so much that the colon is virtually a dual organ and the symptoms of carcinoma vary according to the situation of the lesion, the pathologic type and the presence or absence of complications such as metastasis, perforation or ulceration. The right half of the colon is the absorptive half and is comparable in function to the small bowel with which it has a common embryonic origin. From the papilla of Vater to the middle of the transverse colon the large intestine develops with the small intestine from the midgut and the function of this whole primordium is digestion and absorption. Beyond the middle of the transverse colon the large bowel is developed from the hindgut and its duty is one of storage. The two halves are not only different anatomically so far as the structure of the wall of the bowel is concerned but they leave their blood supply from different sources, the superior mesenteric artery supplying the digestive or absorptive part of the gastrointestinal tract and the inferior mesenteric artery supplying the distal half.

The onset of symptoms usually consists in a but on rare occasions may occur with explosive suddenness and although there are few characteristic early symptoms a warning ordinarily is given by a change of bowel habit or irregularity of the bowel such as mucous diarrhea, or alternate periods of diarrhea and constipation. Chronic diarrhea in an elderly person frequently proves to be due to a malignant growth and the aplorism of Morson. Increasing constipation of recent origin in an elderly person only overcome by purgatives suggests malignant disease of the colon. It is equally true. Approximately 90 per cent of carcinomas of the entire colon present no more definite symp-

penetration perforation or the formation of abscess. On the other hand in the distal segment of the large bowel carcinoma usually originates close to the mucosal border and spreads laterally diminishing the size of the lumen and consequently producing chronic subacute and even acute obstruction (Fig 577 B). One may however occasionally encounter a polypoid lesion.

Multiple primary carcinomas of the colon may occur and although they are not often recognized the possibility of such multiplicity of lesions should be kept in mind since it has a significant bearing on prognosis. Birge and Rankin have reported 16 such conditions in the large intestine. Volvulus and intussusception occur quite frequently as complications of carcinoma of the colon.

Approximately 5 per cent of carcinomas of the colon and rectum are of the mucoid type. Its tendency to recurrence once the regional lymphatic vessels are invaded is most marked.

Eventually regardless of pathological type ulceration and secondary infection develop. The infection is at first localized but may terminate in spreading suppuration, fistulous tracts or peritonitis. Obstructing carcinomas may produce dilatation and hypertrophy of the intestine above the growth (Fig 577 B). Instead of hypertrophy the intestinal wall may be markedly attenuated above the growth and the mucosa may present a moth eaten appearance because of innumerable small ulcers.

Metastasis in carcinoma of the colon as a rule occurs later than carcinoma of any other portion of the gastrointestinal tract. The lymphatic vessel gauge the extent of the lesion and their invasion influences the prognosis considerably. However distant metastasis even to the liver has been noted although the lymph nodes were not involved. The lymphatic structures of

the cecum and appendix according to Pourier and Cunio are more extensively developed than those of the other segments of the large intestine yet metastasis from the cecum is among the slowest of any segment of the large bowel. It would seem therefore that rich lymphatic supply is a defensive mechanism and unfavorable to prognosis because it holds in check the invading malignant growth.

It is highly important to subject nodes and tissues to microscopic examination during operation in order to ascertain if one is working in an invaded area. A detailed consideration of lymphatic metastasis may be found in the section on Carcinoma of the Rectum.

Symptoms.—To record in sequence the chain of symptoms caused by carcinoma of the large bowel is difficult if not impossible particularly if it is desired to emphasize merely the earlier manifestations of the disease.

The reasons for this are that developmentally and ontologically the right and left halves of the bowel differ so much that the colon is virtually a dual organ and the symptoms of carcinoma vary according to the situation of the lesion, the pathological type and the presence or absence of complications such as metastasis, perforation or ulceration. The right half of the colon is the absorbing half and is comparable in function to the small bowel with which it has a common embryonic origin from the papilla of Vater to the middle of the transverse colon. The large intestine develops with the small intestine from the foregut and the function of the whole division is digestion and absorption. Beyond the middle of the transverse colon the large bowel is developed from the hindgut, and its duty is one of storage. The two halves are not only different anatomically so far as the structure of the wall of the bowel is concerned but they derive their blood supply from different sources: the superior mesenteric artery supplying the digestive or absorptive part of the gastrointestinal tract and the inferior mesenteric artery supplying the distal half.

The onset of symptoms usually is insidious but on rare occasions may occur with explosive suddenness and although there are few characteristic early symptoms a warning or warning is given by a change of bowel habit or irregularity of the bowel such as mucus, diarrhea, or alternate periods of diarrhea and constipation. Chronic latraria in an elderly person frequently proves to be due to a malignant growth and the aphorism of Monro "Increasing constipation of recent origin in an elderly person only overcome by purgatives suggests malignant disease of the colon" is equally true. Approximately 25 per cent of carcinomas of the entire colon present no more definite symp-

times in the early stages of the disease. The obvious corollary to this is that thorough investigation of the gastrointestinal tract should be made if a change in intestinal habit or irregularity persists over a period of weeks.

Right Half of the Colon—In this segment of the bowel the large flat ulcerating growths present a wide surface for absorption thus interfering with the function of the mucous membrane and giving rise to profound intoxication and anemia without a tendency to produce obstruction.

In most cases the symptoms of carcinoma in the right side of the colon may be classified under three main groups: (1) so-called "dyspepsia" mild in character with few localizing symptoms and usually diagnosed as chronic appendicitis or chronic cholecystitis; (2) profound anemia, loss of weight and loss of strength; and (3) a mass accidentally discovered in the right iliac fossa which on further investigation proves to be a neoplasm.

The first group represents a high percentage of latent unsuspected cases of carcinoma of the right half of the colon which may be interpreted early if the advisability of roentgenologic examination is urged. There may be an more warning other than a change in bowel habit or bowel irregularity or alternating periods of diarrhea and constipation. Pain and local tenderness simulating subacute or chronic appendicitis without a tendency to disappear occasionally are found to be the early signs of cecal carcinoma.

In the second group that characterized by anemia, weakness and loss of weight one element is outstanding—profound anemia with a concomitant decrease in the entire blood picture yet without visible loss of blood. Attention may be called to such anemia by the patient's inability to carry on his work or by unexplained weakness or it may be found on examination without apparent cause. An exact explanation of this type of anemia cannot be given but it is probably due in part to some perverted or inhibited function of the mucous membrane which impairs it to such an extent that absorption of toxins from the broad infected surface of the growth occurs, the work of Whipple, Schmidt, Koons and others has demonstrated this fact.

In the third group the condition is accidentally discovered in the right iliac fossa by the patient or during a routine physical examination.

Left Half of the Colon—The syndrome of neoplastic growths of the left half of the colon is evidenced more by acute subacute or chronic symptoms of obstruction than by physiologic disturbances. Borborygmi and visible peristaltic movements associated with increased flatulence are of frequent occurrence. Visualization of peristalsis is possible only if the patient is lean.

Progressive constipation occurs in a high proportion of these cases, probably between 25 and 50 per cent and should call attention to the presence of some mechanical stenosis in the majority of cases before roentgenologic evidence is sought. The obstruction may be either acute or chronic. If it is the former it may be due to volvulus, intussusception, plugging of the lumen of the bowel by a foreign body or edema due to an inflammatory process superimposed on the malignant condition. The chronic form of obstruction occurs in a considerable number of cases of carcinoma of the colon owing to direct encroachment on the lumen of the bowel and dependent on the pathologic type and rapidity of the growth. Acute intestinal obstruction secondary to malignant growth is an extremely grave condition and in the writer's experience occurs in approximately 5 per cent of cases of carcinoma of the large bowel. The chances are 6 to 1 according to Burgess that the lesion is to the left side of the colon if it is the etiological factor to be considered.

Blood in the stool is a symptom which is usually emphasized in any consideration of carcinoma of the large bowel. It is the writer's conviction that blood must be bright red or that continual tests for positive occult blood must be made before significance can be attached to its presence. Blood in the stool may come from any portion of the alimentary tract. If tests for occult blood give positive results the lesion may be anywhere between the buccal cavity and the rectum and in the writer's experience this has been of more significance in the diagnosis of unusual tumors of the small bowel than of lesions of the colon and rectum. Tenesmus as a symptom of carcinoma of the colon is

not significant except when the growth is close to the rectum.

The tendency to perforation and formation of abscess in this segment is common. Ulceration aggravated by constant irritation of the solid column of feces progresses to subacute perforation in many instances.

It cannot be too strongly emphasized that symptoms such as great loss of weight, cachexia, dehydration and desiccation commonly set down in textbooks as symptoms of carcinoma of the large bowel are in reality symptoms of metastasis and an approaching lethal state and that the respon-

Fig. 578.—Annular carcinoma of the sigmoid.

sibility of waiting for the development of such a chain of evidence to establish a diagnosis of carcinoma falls on the examining physician.

Diagnosis.—Roentgenologic examination is the most satisfactory single diagnostic aid for growths beyond view with the proctoscope, namely the middle of the sigmoid flexure. Although certain combinations of well known symptoms and signs are unquestionably suggestive diagnostically, careful roentgenologic examination is virtually indispensable for decisive determination of the exact situation of a growth. Roentgenograms reveal a permanent filling defect that

is almost pathognomonic of carcinoma (Fig. 578). The opaque enema is by far the most accurate method of diagnosis and further more in obstructing growths the oral meal is a positive menace since it may produce acute intestinal obstruction superimposed on a chronic process.

A differential diagnosis must be made in the main from hyperplastic tuberculosis of the colon, diverticulitis, polyposis, syphilis, segmental ulcerative colitis, chronic retrocecal appendicitis (which is associated with intermittent symptoms and a palpable mass) and actinomycosis.

Treatment.—Surgical removal of carcinoma of the colon unquestionably precedes all other measures from the standpoint of curability. If a lesion cannot be removed in a radical manner that is by extirpation of the local growth and lymph nodes in the immediate juxtaposition a side tracking operation or some palliative measure often may be employed.

Operability and Prognosis.—Operability of carcinoma of the colon depends on distant metastasis, lymphatic involvement, local attachment of the growth and the resistance of the patient. Obviously, extensive operation for carcinoma of the colon should not be undertaken without a thorough preliminary exploration of the liver and pelvis for metastasis. All nodes should be subjected to careful microscopic study. Attachment to the abdominal wall involves a more serious risk and may be due to perforation of the growth or to inflammatory reaction. It is not incompatible however with satisfactory end results to resect a large portion of the anterior or lateral parietes provided there is not a better reason for excluding a radical operation. Broders' index of grading malignancy (see section on Carcinoma of the Rectum) permits one to recognize at the operating table types which are favorable and types which are unfavorable from the standpoint of prognosis. In a study of 753 cases of cancer of the colon Rankin and Olson found that the percentage of five year cures in growths which projected into the lumen was 42 per cent against 41 per cent for growths that extended toward the serosa.

It should be borne in mind that factors other than the technical performance of the operation such as the patients' general con-

dition ofesity and age are important. The general condition of the patient as evidenced by the degree of anemia and dehydration attendant on the concomitant intoxication from obstruction is significant in influencing operability. Anemia commonly associated with the right segment of the colon is not a contraindication to exploration and resection even though the concentration of hemoglobin is as low as 25 to 30 per cent. On the other hand anemia in a case of carcinoma of the left half of the colon is a contraindication against resection. Given the same pathologic process in two patients of the same age and otherwise apparently equal chances it is found that the older patient is a greater operative risk with a poorer outlook from the standpoint of ultimate cure. Age influences greatly the prognosis of carcinoma of the colon. The clinical observation has been proved many times that the younger the patient the more rapid the growth and the more widespread the dissemination. When the lymphatic structures of advanced age have undergone atrophic changes and are no longer active carcinoma is held in check and remains local for a much longer period than when the subject is young and possesses vigor and vitality.

Additional factors which influence immediate prognosis in operating on the colon are: (1) adequate preoperative rehabilitation combined with the necessary decompression measures; (2) selection of the optimal time for operation and selection of the operation for the patient rather than an attempt to standardize procedures and to fit cases of carcinoma in one or two manners; (3) employment in a large number of cases of operations in multiple stages; (4) selection of an anesthetic suitable to the individual case; and (5) rigid adherence to a standardized postoperative regimen.

Choice of Operation.—Several factors influence the choice of operation in the two parts of the colon. The matter of graded operations on each side however is of greatest importance. It is now generally agreed that graded procedures in surgery of the colon and rectum enhance markedly the final satisfactory outcome. That this must be accomplished frequently with disregard of the economic situation of the patient and of the

profits of both patient and physician against prolonging the convalescence is unquestionable and yet ultimately to accomplish either cure or prolonged palliation must be the aim of all surgical procedures.

In operating on the right half of the colon it is the writers' feeling that ileocolostomy between the terminal ileum and the transverse colon followed by resection of the right segment at the same or a subsequent stage is the procedure of choice. Whether the resection is to be done at once or subsequently is a decision which must be made at the operating table in each case on its own merits. The employment of end to side anastomosis rather than lateral anastomosis is preferred in this particular instance because of the desirable features which the end to side method possesses over the lateral in side tracking the fecal current and allowing as much reduction of local inflammatory reaction around the growth as is possible. Where over the end to side union more nearly approximates the natural anatomic relationship of ileum and cecum.

In the left half of the colon where obstruction is the most alarming symptom the problem is different. If the obstruction is acute and the bowel dilated edematous and filled drainage by cecostomy or colostomy proximal to the growth is urgently indicated. If on the other hand as happens in the majority of cases the obstruction is mild and has been relieved by preoperative measures resection frequently may be accomplished in one stage but without anastomosis. The writers do not believe that primary anastomosis should be carried out on the left half of the colon except in extremely rare instances and when it is a cecostomy or colostomy proximal to it is always indicated. Simultaneous decompression with the Miller Abbott tube is commendable as an additional safeguard but should not be employed as a substitute for cecostomy or colostomy which are more uniformly dependable.

It is apparent that the advent of sulfasuxidine has led some to abandon entirely the principles of multiple stage procedures notwithstanding the fact that the uncertainty in regard to the blood supply of the divided ends of the colon continues to make primary anastomosis a hazardous undertaking. It is our firm conviction however that

the economic factor in dealing with carcinoma is one which may be disregarded advantageously when the time comes to select operative procedures for by spending more time preoperatively and in carrying out multiple operations lower mortality and a higher percentage of satisfactory end results may be the reward.

In the average case in a mobile segment of bowel the procedures available are (1) obstructive resection (Rankin) (2) a cecostomy followed two or three weeks later by resection and anastomosis (3) an exteriorization operation such as that described by Paul Block or Mikulicz. Frequently in this country all such procedures are erroneously referred to as the Mikulicz operation.

Obstructive resection combines the desirable features of the old type of exteriorization operation in one stage making it a radical operation removing the growth and gland bearing tissue together and leaving the bowel obstructed for a period of from forty-eight to seventy-two hours. In the event of obstruction unrelieved by medical measures it will of course be necessary to resort to cecostomy before such a procedure is employed. The usual exteriorization operation is merely a local excision and is accompanied by a high mortality when a large series of cases is considered. At the same time it resulted in recurrence of the growth in the abdominal wall in 12 per cent of a large series of cases and a high percentage of recurrences of intra-abdominal malignant lesions because of failure to accomplish widespread block dissection of the gland bearing tissues in juxtaposition to growth.

Operative Procedures—It is always inadvisable to hospitalize the patient for a period of time sufficient to enable decompression of the obstructed colon and restoration of the hypertrophied and often edematous bowel to a healthier state to combat dehydration and the effects of malnutrition and to permit an investigation of the function of the other organs of the body. The importance of such a practice as a routine cannot be overestimated. A satisfactory regime during this preoperative interval briefly is as follows: (1) repeated colonic irrigations with normal saline solution. (2) high caloric low residue diet consisting chiefly of

carbohydrates (3) forced fluids orally subcutaneously or intravenously, (4) transfusions when indicated (5) special measures directed toward overcoming concurrent disease in the other organs (6) sulfadiazine parenterally if the sulfonamides are employed because the effectiveness of these drugs depends in great measure upon the systemic presence of the drug consequently they are definitely more dependable than sodium sulfathiazole (sulfasulazine).

Measures of Decompression—The dangers of increased intracolonic pressure may be minimized by the establishment of a safety valve in the intestine such as that resulting from appendicostomy, cecostomy, ileostomy or colostomy (Fig. 579). This may be accomplished several days or weeks prior to resection depending on the degree of obstruction present or it may be done at the time of resection as an additional precaution. Cecostomy is the procedure more generally favored.

1 **Appendicostomy**—The appendix is delivered through a McBurney incision as for appendectomy and the wound closed in layers about the protruding organ. In case of urgent necessity the appendix may be divided at once and a catheter introduced otherwise it is best to wait for forty-eight hours.

2 **Cecostomy**—Cecostomy may be accomplished satisfactorily by one of several methods (Gibson, Hendon, Witzel or Hader) with small likelihood of the subsequent formation of a fistula. A right rectus or a McBurney incision may be employed. A No. 30 French soft rubber catheter is placed in the cecum and held by a purse string suture which also inverts the inner wall of the cecum.

If the Gibson technique is employed two other layers of sutures extend from the tube up and down the bowel so as to form a broad surface which will adhere to the peritoneum (Fig. 579). The Witzel technique as applied to the cecum is identical with the widely employed ileostomy of the same name which is described elsewhere. In performing cecostomy it is the writer's custom to use a large mushroom catheter after having cut off the top of the mushroom portion a procedure suggested by Hendon. The cuff-like structure which is left at the end of the

catheter prevents the tube from coming out before the desired time.

3. *Ileostomy*—The choice of methods depends on whether the ileostomy is to be permanent or temporary. As a preliminary procedure to total resection of the colon for multiple malignant growths the writers prefer the simple technique shown in figure 579. The John Young Brown and Harvey Stone methods are more complicated and are per-

rectum is the most usual procedure. However, colostomy may be advantageously performed in the transverse colon as a procedure substituted for ectostomy and appendicostomy for an obstructive lesion of the left half of the colon. Fecal control following colostomy has been the object of ingenious procedures directed toward the manufacture of a sphincter muscle. This however is not necessary for if the bowels

Fig. 579.—Measures of decompression. a. Gibson resection: permanent ileostomy; the cecal end of the ileum is inverted, the terminal ileum is brought out at a McBurney incision; in a left inguinal colostomy the peritoneum and skin are approximated and sutured separately beneath the sigmoid; no sutures are placed in the bowel.

formed with the idea of subsequent reestablishment of the continuity of the intestinal current. The Witzel type of enterostomy is usually satisfactory as a temporary measure, particularly when established in the terminal ileum proximal to the suture line in resection of the right half of the colon.

4. *Colostomy*—Establishment of colostomy in the sigmoid flexure through an inguinal incision preliminary to resection of

are trained to be constipated, the results of colostomy regardless of the type are usually satisfactory. The simplicity of the left inguinal colostomy commends it. Moreover, herniation or weakness of the abdominal wall about the stoma is far less frequent than when colostomy is established in the right rectus muscle.

In performing left inguinal colostomy an incision comparable to the McBurney split

muscle incision is made in the left lower quadrant of the abdomen. The sigmoid is brought out of the incision until its most fixed position close to its juncture with the descending colon is reached. The sigmoid distal to this point of mesenteric attachment is at the same time fed back into the abdomen. In this manner it is possible to insure against herniation of the mucous membrane of the proximal loop.

With the aid of a pointed forceps a hole is made in the mesosigmoid and a rubber tube is pulled through and retained for traction on the bowel during the remainder of the procedure at completion of which a glass tube is substituted for the tubing. The peritoneum at the middle of the incision is pulled under the bowel through the rent in the mesosigmoid and sutured to the peritoneum of the opposite side (Fig. 579). In the case of a permanent colostomy the skin in a similar manner is pulled under the lifted loop of bowel and sutured in skin with silk worm gut. The abdominal wound is closed loosely around the bowel. Stitches are not placed in the bowel. The bowel is opened with a cautery usually forty-eight to seventy-two hours later.

Measures of Extirpation of the Colon.
A Resection of the Right Side of the Colon.—The operation if in one stage or two stages consists of two distinct procedures: (1) ileocolostomy by which continuity of the lumen of the bowel is restored and (2) mobilization and resection of the right side of the colon and the anastomosis can be made end to end, end to side or laterally; it can be accomplished by the open suture method or with a Murphy button by a closed method such as the Parker-Kerr basting stitch or by means of the Rankin clamp. The open suture method of anastomosis has been adequately described elsewhere in relation to resection of other portions of the gastrointestinal tract. The relative safety and simplicity of the clamp method which the writers have employed with a high degree of satisfaction for over ten years commend it.

1 Ileocolostomy (Rankin clamp method).—The terminal portion of the ileum about 10 cm. from the ileocecal valve is divided between clamps, one of which is the special three-bladed clamp (Fig. 580 A). The end

toward the cecum is inverted and dropped back to be removed with the colon. A point selected on the anterior surface of the transverse colon is fixed by the other blade of the clamp containing the ileum and an elliptical piece of the colon is removed with a cautery to make an opening in its lumen. Sutures are then applied anteriorly and posteriorly separately. As the clamp is opened and withdrawn the two free ends of the anterior sutures are drawn taut thus inverting the two ends of the bowel. A layer of sutures is then inserted around the entire end to side anastomosis.

2 Mobilization and Resection of the Right Side of the Colon.—This constitutes the second stage of the clamp method and is accomplished either immediately on completion of the ileocolostomy or at a second stage (Fig. 580 A). The peritoneal attachments to the lateral abdominal wall are divided and the whole colon is rotated mesally, the fat and lymphatics being wiped inward with gauze. The spermatic vessels come into view at the lower angle of the wound and as dissection is carried upward the ureter is observed. In mobilization of the hepatic flexure of the colon the second portion of the duodenum is revealed and must be studiously avoided since injury to this structure is corrected with difficulty and carries with it a high mortality. The mesenteric blood vessels are clamped and ligated as they present themselves. A satisfactory point is chosen in the transverse colon proximal to the anastomosis between the ileum and colon and the bowel is divided between clamps with a cautery. The distal end of the divided transverse colon is inverted and brought into the upper end of the abdominal wound as it is closed. The raw surfaces should be peritonized.

B Resections of the Left Side of the Colon.—The high incidence of peritonitis subsequent to opening the colon together with the uncertainty in regard to the blood supply of the divided ends makes primary anastomosis of the colon by either the open or the closed method highly dangerous. However, if such an anastomosis seems advisable it can be accomplished by: (1) open anastomosis, (2) a Murphy button, (3) closed procedures such as the Parker-Kerr basting stitch and (4) the

Fig 380.—A Ileocolostomy, Rankin clamp technique and resection of the right half of the colon. *a* The special clamp one blade of which holds the proximal end of divided terminal ileum is being applied to a point selected on the transverse colon for the colonic end of the anastomosis. The elliptical portion of colon that will protrude above the clamp is removed with a cautery. The cecal end of the divided ileum is being inverted. The insert shows the anterior layer of sutures. The posterior layer having been applied first. *A*, inverted posterior suture. *B*, anterior suture. *b* Beginning mobilization of the cecum and ascending colon after incision through the parietal attachment of bowel. Primary ligation of the main arteries simplifies the operation. End to side ileocolostomy has been established. *c* Resection of the right half of the colon is completed and the raw surfaces left by the dissection have been closed with a continuous suture. An enterostomy has been established in the ileum just proximal to the anastomosis. *B* Exteriorization procedures which necessitate re-establishment of the bowel continuity and closure of colostomy. *a* The so-called Mikulicz type of exteriorization. *b* obstructive resection employing the Rankin clamp. *c*, application of clamp to the septum separating the approximated loops of bowel. *d*, the septum has been removed and bowel continuity restored.*

muscle incision is made in the left lower quadrant of the abdomen. The sigmoid is brought out of the incision until its most fixed position close to its juncture with the descending colon is reached. The sigmoid distal to this point of mesenteric attachment is at the same time fed back into the abdomen. In this manner it is possible to insure against herniation of the mucous membrane of the proximal loop.

With the aid of a pointed forceps a hole is made in the mesosigmoid and a rubber tube is pulled through and retained for traction on the bowel during the remainder of the procedure at completion of which a glass tube is substituted for the tubing. The peritoneum at the middle of the incision is pulled under the bowel through the rent in the mesosigmoid and sutured to the peritoneum of the opposite side (Fig. 579). In the case of a permanent colostomy the skin in a similar manner is pulled under the lifted loop of bowel and sutured to skin with silk worm gut. The abdominal wound is closed loosely around the bowel. Stitches are not placed in the bowel. The bowel is opened with a cannula usually forty-eight to seventy-two hours later.

Measures of Extirpation of the Colon
A Resection of the Right Side of the Colon
 —The operation if in one stage or two stages consists of two distinct procedures: (1) ileocolostomy by which continuity of the lumen of the bowel is restored and (2) mobilization and resection of the right side of the colon and the anastomosis can be made end to end, end to side or laterally. It can be accomplished by the open suture method or with a Murphy button by a closed method such as the Parker-Kerr hasting stitch or by means of the Rankin clamp. The open suture method of anastomosis has been adequately described elsewhere in relation to resection of other portions of the gastrointestinal tract. The relative safety and simplicity of the clamp method which the writers have employed with a high degree of satisfaction for over ten years commend it.

1 Ileocolostomy (Rankin clamp method)
 —The terminal portion of the ileum about 10 cm. from the ileocecal valve is divided between clamp, one of which is the special three-bladed clamp (Fig. 580 A). The end

toward the cecum is inverted and dropped back to be removed with the colon. A point selected on the anterior surface of the transverse colon is fixed by the other blade of the clamp containing the ileum and an elliptical piece of the colon is removed with a cautery to make an opening in its lumen. Sutures are then applied anteriorly and posteriorly separately. As the clamp is opened and withdrawn the two free ends of the anterior sutures are drawn taut thus inverting the two ends of the bowel. A layer of sutures is then inserted around the entire end to side anastomosis.

2 Mobilization and Resection of the Right Side of the Colon—This constitutes the second stage of the clamp method and is accomplished either immediately on completion of the ileocolostomy or at a second stage (Fig. 580 A). The peritoneal attachments to the lateral abdominal wall are divided and the whole colon is rotated mesally, the fat and lymphatics being wiped inward with gauze. The spermatic vessels come into view at the lower angle of the wound and as dissection is carried upward the ureter is observed. In mobilization of the hepatic flexure of the colon the second portion of the duodenum is revealed and must be studiously avoided since injury to this structure is corrected with difficulty and carries with it a high mortality. The mesenteric blood vessels are clamped and ligated as they present themselves. A satisfactory point is chosen in the transverse colon proximal to the anastomosis between the ileum and colon and the bowel is divided between clamps with a cautery. The distal end of the divided transverse colon is inverted and brought into the upper end of the abdominal wound as it is closed. The raw surfaces should be peritonized.

B Resections of the Left Side of the Colon—The high incidence of peritoneal infection subsequent to opening the colon together with the uncertainty in regard to the blood supply of the divided ends makes primary anastomosis of the colon by either the open or the closed method highly dangerous. However if such an anastomosis seems advisable it can be accomplished by: (1) open anastomosis, (2) a Murphy button, (3) closed procedures such as the Parker-Kerr hasting stitch and (4) the

writers clamp method. To obviate the dangers incident to increased intracolonic pressure in such procedures either cecostomy or colostomy proximal to the anastomosis should be provided. Procedures which can be used instead of primary anastomosis are (1) the old type exteriorization operation and (2) the obstructive resection of Rankin. The open suture method of anastomosis has been adequately described elsewhere in relation to resection of other portions of the

Fig. 581. Obstructive resection of the colon. The special clamp is seen applied to the two ends of bowel and a cecostomy is being performed. The mesenteric blood vessels have been ligated near their points of origin and a wide expanse of mesentery has been sacrificed along the segment of colon harboring the growth. The insert shows the wound closed and the clamp in situ, the handle of which rests upon the abdomen.

gastrointestinal tract. The obstructive resection utilizes all the satisfactory fundamental principles of the exteriorization operation yet avoids its disadvantages. It is applicable to any portion of the colon that is mobile or mobilizable.

1. Obstructive Resection of the Colon.—The segment of the bowel harboring the growth is delivered into the wound after the peritoneal attachments to the lateral abdominal wall are divided in order to insure mobility. The vessels are then ligated

close to the root of the mesentery and the intervening expanse of mesentery with its regional lymph nodes is widely excised. The special three-bladed clamp which the writers use for aseptic anastomosis is applied to the two limbs of colon (Fig. 581), care being taken at this stage to insure a good blood supply to the two ends of the bowel. Just above this clamp another is placed and between these the bowel is divided with a cautery. The rent in the mesentery is closed and all raw surfaces are peritonized. The clamp is then brought out of the wound, the edges of which are approximated snugly above the limbs of bowel; no stitches actually being taken in the colon. The bowel is then left totally obstructed for at least forty-eight hours and usually for as long as seventy-two hours. Untoward symptoms will not develop if proper preoperative cleansing measures have been carried out. In those cases of obstruction in which the patient fails to respond to preoperative treatment, cecostomy should be resorted to before the obstructive resection is attempted. The remainder of the operation is accomplished as in the exteriorization procedure; that is, the spur is cut with an enterotome or with clamps and after at least a month the fistula is closed surgically, provided a spontaneous closure has not already taken place.

2. Exteriorization Operation.—The growth-containing segment of bowel is delivered into the abdominal wound as in the obstructive resection but the mesenteric blood vessels and lymphatic structures are left intact. The abdomen is then closed tightly around the extruded mass which is surrounded with petrolatum gauze in an attempt to prevent transplantation of carcinoma cells to the abdominal wall. The second stage, which may be performed any time after forty-eight hours, consists in the removal of the protruding bowel flush with the abdomen. The third stage entails removal of the intervening partition between the two loops of bowel with clamps and finally closure of the colonic stomas.

Mortality and Recurrence.—See section on Carcinoma of the Rectum.

XXIX ANAL CANAL AND RECTUM

ANATOMY, CLARIFICATION OF TERMS ETC

Doctors and medical students alike are frequently guilty of considerable laxity in their use of proctologic terminology. Perhaps they feel that careful differentiation of anorectal terms is of academic interest only. In reality they would be amply repaid by a simpler conception of symptomatology of diagnosis and of treatment of anorectal disease if they were willing to learn the funda-

Fig. 563—A schematic representation of the anorectal canal (coronal section)

mental principles of anatomy and of nervous physiology as applied to the anorectum.

Study of the developmental anatomy has shown that the anal canal is derived from the embryonic proctodaeum hence anal structures are ectodermal in origin. The rectum is entodermal in origin being derived from the hindgut. The anal plate which early occludes the anorectal outlet disintegrates at about the seventh week of fetal life. Complete or partial failure of these processes accounts for the variety of anomalous defects occasionally seen e.g. an imperforate anal canal.

The anal canal forming the terminal por-

tion of the intestinal tract varies in length from 1.5 to 2.5 or 3 cm. Its superior border is the *dentate margin* the inferior boundary is the *anus* or anal verge the anus being considered a *rima* in the anatomic sense (Batson¹). The *anal canal* is lined by skin not by mucous membrane—the term *anal mucous membrane* being a misnomer. The *dentate margin* comprises the anal semilunar valves and the anal papillae together with the anal crypts (Morgagni). There are several terms used synonymously with *dentate margin* namely *pectinate line* and *rectal line* and *mucocutaneous line* or *border*. The term *white line of Hilton* refers to the *intersphincteric line* it is not synonymous with the aforementioned terms and had best be forgotten in order to avoid further confusion (Fig. 563).

Nervous Physiology.—The skin lining the anal canal investing the anal papillae and partially lining the anal crypts receives a somatic sensory nerve supply. Accordingly, therefore nearly all lesions involving anal structures are painful notably thrombosis of an external hemorrhoidal vein, anal fissure, anal abscess, cryptitis, papillitis, etc. The mucous membrane of the rectum is believed to be supplied by visceral sensory nerves. It is not surprising then that rectal lesions except those that involve also the dentate margin are not accompanied by pain early in their course. Likewise internal hemorrhoids can be injected and polyps can be fulgurated without anesthesia. Somatic motor nerves supply the external anal sphincter and the levator ani muscles (striated) whereas the internal sphincter muscle (smooth) and the rest of the smooth muscle of the gut receive a visceral motor nerve supply.

CRYPTITIS, PAPILLITIS AND
FISSURE IN ANO

Cryptitis.—The crypts of Morgagni are of the utmost importance in the etiology of infectious anorectal diseases. Because each of the crypts has a blind pouch at its lower end which easily catches and retains foreign particles of all kinds and because the crypts are subjected to traumatization by hard stools infection is not uncommon. The infection is usually due to ordinary pyogenic organisms although tuberculous and gonorrheal infections are not infrequent. In case of tuberculous infection a fistula usually develops promptly. Gonorrheal infection is accompanied by proctitis. The gonococcus is usually quickly overgrown by other organisms found in the rectum and the proctitis subsides but chronic cryptitis remains.

The usual symptoms of chronic cryptitis are the feeling of vague discomfort and heaviness in the rectum with low grade dull pain radiating into the buttocks and perhaps down the back of the thighs. When a single crypt is involved the discomfort can be definitely located in one limited area. Periods of remission and exacerbation of symptoms are a definite characteristic of this disease. A small amount of mucus either tinged with blood or not may be noticed on the first part of the stool but often this is not present. Digital examination will reveal each involved crypt to be definitely tender on pressure. On examination with a bivalve speculum so that the folds and crypts are spread open their bases are seen to be red and granular. The mucosa lining the crypt bleeds more readily than normally, and a blunt hook will reveal particularly in the lower pocket-like portion varying degrees of tenderness. It is from such a diseased crypt that many other anorectal diseases develop. Anal fistulas in particular are almost always the result of cryptitis. After the crypt becomes infected the infection may spread through its wall by direct continuity through the small tubular ducts or by way of the lymphatics and then form a perirectal abscess. When this abscess ruptures or is incised the cycle of fistula formation is completed. If the infection is of low virulence and if when it penetrates the wall of the crypt it extends downward just

beneath the anoderm* rather than invading the deeper structures a fissure will result. The actual fissure is produced when the anoderm over the infected area becomes friable and breaks down thus leaving a typical shallow ulcer.

The extent of the importance of cryptitis in the formation of the so-called idiopathic type of ulcerative colitis has not been definitely determined. The originating of ascending proctitis in cryptitis is relatively frequent. Another condition resulting from cryptitis is narrowing or stricture of the rectum just at the anorectal juncture a condition commonly called *pectinosis*.

The treatment of cryptitis is both surgical and medical. In the writer's experience except in the acute cases or the mildest type of the more chronic cases medical treatment is usually unsatisfactory in so far as permanent results are concerned. The medical treatment which offers the best hope of good results is irrigation of the rectum with warm solutions of boric acid or potassium permanganate or the injection of an ounce of 1 to 200 aqueous solution of metaphen. 0.5 per cent mercurchrome or 10 per cent ergyrol. In addition the physician should see the patient frequently dilating the anal canal and the lower portion of the rectum with a bivalve speculum. With the crypts thus spread open their bases should be swabbed with silver nitrate (1 to 10 per cent). The difficulty with all medical treatment lies in the fact that at the lower end of each crypt lies a pocket or pouch which does not drain adequately and hence is difficult to clear of infection. The removal of this pocket and the securing of adequate drainage of the entire crypt will usually result in permanent cure. This operation may be done in the physician's office a local anesthetic being used though for a nervous patient twenty-four or forty-eight hours of hospitalization may be advisable. A number of methods of operation are advised but the most simple and satisfactory method is the following. A hooked probe is inserted into the pocket of the crypt. The flap of the pocket is then raised on the hook and removed in its en-

*The anoderm the epithelial lining of the anal canal differs from ordinary skin in that the former has neither hair follicles nor sweat glands and its epithelial cells are flatter.

tirely with curved scissors. It is important that the cut edges of the pocket be kept from adhering together and this can be accomplished by frequent digital examination and the palpation of each crypt which has been operated upon. The use of some astringent ointment such as nupercaine (1 per cent) and a mild antiseptic such as metaphen is usually all the postoperative care necessary. The patient, however, should be seen frequently until healing is complete.

Papillitis—Papillitis is inflammation of the anal papillae which are serrated projections resulting from the breaking down of the anorectal membrane. They are covered with squamous anal epithelium hence they are anal rather than rectal in origin and therefore very sensitive. There is considerable normal variation in the size of these papillae both in different persons and in the different papillae in the same person. When a papilla is quite prominent it will often elongate and hypertrophy as a result of inflammation, the passage of the stool and the action of the sphincter muscle until it may be more than an inch in length. Not infrequently there develops a hard fibrous polypoid nodule on its terminal end. When it becomes inflamed either from an infection in an adjacent crypt or because of traumatization by the stool considerable pain and tenderness which are aggravated by defecation are usually noted. A spasm of the sphincter is also present which makes the symptoms more severe. Occasionally a tear may develop at the point of attachment owing to the pull on the terminal portion by the passage of a stool or the contraction of the sphincter. This may produce all the symptoms of an anal fissure. The treatment of this condition is removal of the offending papillae. This can be accomplished with the use of a local anesthetic; the after treatment being essentially the same as that following excision of a crypt.

Fissure In Ano.—While it is true that any crack in the anal skin is a fissure for practical purposes it is well to make a distinction between acute anal or perianal cracks and what should be termed a true fissure in ano. In many persons a crack or abrasion develops following the passage of a hard stool or from some condition which irritates the anal or perianal skin. In thin

skinned persons or those suffering from pruritus ani or other cutaneous conditions about the anus this may occur rather frequently. However if the stool is kept soft and mild applications are used these cracks readily heal. A fissure originates in one of two ways. First, it may originate from an infection of a crypt of Morgagni in which the infection burrows down underneath the anoderm. The tissue over this small sinus breaks down forming an ulcer. Usually a portion of the anoderm over the upper part of the sinus opening into the crypt remains intact. This portion of the tract is in fact a tiny subcutaneous fistula. If then at any time the broken down ulcerated area should heal the little fistula draining into it will cause it to remain infected and to break down again. Hence the futility of local applications in this type of case. There is always a small amount of secretion from a fissure and this causes an inflammatory tub to form at the lower end. It is tiny to begin with but may grow to the size of the end of the little finger—the so-called sentinel pile.

The second type of fissure usually develops from a crack or abrasion in the anal canal caused by trauma. In these cases anal stenosis is almost invariably present. If it does not heal promptly the secretion causes a sentinel pile to develop. If anal stenosis is present recurrence of the fissure is certain unless every stool is kept soft. Since it is practically impossible for a patient to avoid an occasional hard stool recurrence of the fissure is almost inevitable unless the anal stenosis is relieved. Anal stenosis therefore demands surgical treatment. Other infectious conditions in the anal canal due to venereal disease, tuberculosis, etc. may produce ulceration but should not be classed with the true fissures. While a fissure may occur at any point in the anal canal the most common site is in the posterior midline. This is probably due to the fact that the fibers of the sphincter cross here or are inserted into the anococcygeal tendon; a larger and deeper crypt is present in this location than elsewhere and elasticity is less. The direction of the anal canal produces greater traumatization by the stool at this point and the blood supply in this region is more scanty.

In those cases which do not result from infection of an anal crypt or in which no sentinel pile has formed and in which anal stenosis is not present medical measures offer some hope of cure. Recently the injection of certain solutions such as 5 per cent quinine urea hydrochloride or the injection of oily solutions such as 5 per cent phenol in olive oil, benzoel nupercaine in oil or buccaine compound has been advocated for use in the treatment of this condition. From 2 to 5 cc of the solution is injected under the base of the fissure. The prolonged anesthetic action relieves pain and spasm and enables the physician to treat the fissure with various applications. However if a sinus is present at the upper end or if a sentinel pile is present at the lower end or if anal stenosis is present the fissure must be operated upon before a cure can be effected. The writer is convinced that in the majority of cases surgical treatment gives the best assurance of permanent cure. At the same time any other rectal and anal pathologic condition which may be present can be cared for. A number of methods of operation have been devised but only the one which the writer has found to be always successful will be described here.

If any pathologic condition other than the fissure is present spinal anesthesia is generally employed. If only the fissure is present, the intravenous injection of 2.5 per cent pentitol sodium is generally used. After anesthesia the anus is dilated but not divided. A blunt hook is inserted into the crypt above the upper end of the fissure to determine whether or not a sinus extends down to it from the crypt. If so the sinus is excised. Any scar tissue in the base of the fissure is dissected out, and if a sentinel pile is present it is removed. A deep longitudinal incision is now made through the base of the fissure dividing a portion of the sphincter. The incision is carried well outside the anus. The edges of the incision are trimmed away carefully enough so that no packing is necessary. Bleeding vessels are secured but no other stitches are used. It is desirable to produce a good sized wound which does not tend to close over too readily. In many cases postoperative difficulties develop because the procedure has not been radical enough. The postoperative care in these cases consists of hot sitz baths twice daily beginning twenty-four hours after operation on the injection of enema mineral oil to insure soft evacuations and local treatment with various applications such as mercurochrome (2 per cent) and thymol iodide dusting powder. Complete healing of the wound is usually obtained in about three weeks.

ANAL FISTULA (FISTULA IN ANO)

The Latin word *fistula* means pipe and a piece of pipe has two openings—one at either end. Accordingly therefore the term blind internal fistula or blind external fistula as applied to a tract which ends blindly is a misnomer; the proper term in this instance being sinus. Practically all anal fistulas originate in an anal crypt—hence the term *fistula in ano*.

There seems to exist considerable misunderstanding with regard to anal fistulas and to abscesses which occur in the tissues surrounding the anal canal and rectum. A thorough understanding of the pathogenesis of anal fistulas will simplify the problem and will facilitate treatment. Abscess formation is a definite step in the establishment of fistula in ano; hence the very logical reason for describing abscesses under the heading of fistula in ano.¹

Stage I. Infectious material invades the anal crypt and the tiny vestigial anal ducts attached thereto.

Stage II. The infection is carried into the surrounding tissues by way of the lymphatics.

Stage III. The infected tissue (usually loose fatty areolar tissue) breaks down into an abscess; the signs and symptoms of which are familiar to every physician—redness, local heat, swelling, tenderness and pain. It is usually at this stage that the patient first seeks medical aid.

Stage IV. The abscess ruptures spontaneously or is incised. Not until drainage has been established can the term *fistula* be properly applied. One opening of the fistula, namely the infected crypt, is provided in stage I. The other opening occurs in stage IV.

Bue has logically termed the infected crypt the primary opening of the fistula. The other opening (single or multiple) is therefore called "secondary," whether it oc-

curs in the rectal wall above the dentate margin or in the skin about the anus or over the buttock.²

Now that the role played by an abscess (stage III) in the formation of an anal fistula has been discussed, the various locations involved by abscess formation may be considered. There are no true spaces about the anal canal and rectum; hence one speaks of "surgical spaces" as spaces which can be created by dissection or by dissolution of tissue during the infectious process resulting in an abscess. There are five such spaces: the two ischioanal spaces or fossae beneath the levator ani muscles (Fig 583 a, *I.A.*), the two perirectal spaces (Fig 583, a, *P.R.*)

under pressure, because the boundaries of this cavity are fairly rigid. He calls attention further to the fact that the roof of the perirectal space is peritoneum, which is capable of being floated upward.³ Accordingly, therefore, when an ischioanal abscess is incised and a great deal more than 2 or 3 ounces of pus is obtained, one can be reasonably certain that the infectious process has involved a "deep" space (above the levators) as well as a superficial one. Communications between the superficial and the deep spaces occur usually near the anal attachments of the levator muscles.

In figure 583, a the tract labeled *1* leads to an abscess (*Ab*) in the ischioanal fossa

Fig 583—A diagrammatic representation of anal fistulae and of surgical spaces (see text). *P.R.* indicates perirectal space; *I.A.*, ischioanal space or fossa; *Ab*, abscess; *1, 2, 3, 4*, fistulous tracts; *1', 2', 3', 4'*, secondary openings.

and the retrorectal space above the levators (Fig 583, b and c). When one or both ischioanal fossae are involved the signs and symptoms are obvious to both the patient and the physician, as previously described, because of the superficial location of the abscess inferior to the pelvic diaphragm. However, involvement of any of the three deep spaces above the pelvic diaphragm is accompanied only by vague symptoms—a feeling of weight or heaviness in the pelvis and possibly chills and fever. The diagnosis depends upon careful digital palpation, which will disclose a "doughy" swelling encroaching on the rectal lumen. Batson has pointed out that the ischioanal fossa can hold no more than 2 or 3 ounces of fluid even

Drainage is established by the secondary opening *1'*. Tract 2 originates at the usual level in an infected crypt but leads to an abscess (*Ab*) above the levator in the perirectal space on that side. The abscess has ruptured into the rectum at *2'*, which is the secondary opening of the fistula. Tracts 3 and 4 represent diagrammatically the appearance after contraction of the abscess cavities. Hence the primary openings lie in the anal crypts at the level of the dentate margin. Openings at any other place, either on the skin surface or in the rectal wall, are secondary—and the term fistula-in-ano, still holds, because the primary source of the fistula in either case is a crypt, which is an anal structure.

An acute abscess requires drainage. The choice of a point for incision is important. If fluctuation is present an incision should be made at that point but the opening should be made as near the anus as possible in order that the resulting fistulous tract may be as short as possible. In the case of a deep abscess with or without involvement of the ischioanal fossa drainage should be established through the ischioanal fossa on the involved side rather than through the rectal wall. In the case of a retrorectal abscess drainage can be established through the anococcygeal raphe or to either side of it and as near the anus as possible. The author then usually waits for ten or fourteen days before performing fistulectomy.

The treatment of anal fistula is the same regardless of etiology, namely complete exposure of the tract from primary to secondary openings with excision of the overhanging edges so as to create a flat wound. This can usually be done in one sitting and all the existing tracts can be laid open at one time provided of course careful attention is given to after care. An essential feature in fistulectomy is adequate exposure; this is best obtained with either low spinal or sacral block anesthesia. The other types of anesthesia do not permit satisfactory anal relaxation.

There is one notable exception to the foregoing statement in the foregoing paragraph and that pertains to a fistula which is found in a patient suffering from thrombo-ulcerative colitis (chronic ulcerative colitis). It is not wise to undertake anorectal surgical treatment in these cases because the wound will not heal. It is permissible to drain an abscess but to do a fistulectomy, a hemorrhoidectomy or a fissure operation for a patient suffering from chronic ulcerative colitis is definitely contraindicated.

ANORECTAL VENEREAL DISEASE

Syphilis—In dispensary practice one occasionally sees primary syphilitic lesions (i. e. chancre) involving the skin of the anal canal. Condylomata lata are the usual secondary lesions found affecting the anal and the perianal skin. Syphilis of the rectum is rare. Treatment has been well organized by the modern syphilologist.

Gonorrhea—Anal gonorrhea involves chiefly the anal crypts and anal glands. Rectal gonorrhea affects usually only the lower third of the rectum; the process ranging from mild proctitis to partial or complete destruction of the mucous membrane. Sulfonamides constitute the established treatment although penicillin bids fair to become the agent of choice.

Chancroid (Soft Chancre)—These lesions are occasionally seen involving anal or perianal skin as a result of auto-inoculation from a genital lesion although primary implantation in this region is possible. The pain is usually severe. Sulfonamides are practically specific.

Venercal Lymphogranuloma—(See sections on Benign Rectal Stricture and Venereal Lymphogranuloma.)

COMMANDER J. PIERMAN NESSLER

BENIGN RECTAL STRICTURE

Benign strictures of the rectum may be either congenital or acquired; the latter in turn may be either extrinsic or intrinsic in origin. Any extrarectal process, whether neoplastic or inflammatory, can encroach on the rectum with resultant narrowing of its lumen. In these instances however the rectal mucosa is usually intact, being involved only secondarily when there is malignant invasion of the rectal wall. Benign strictures which are intrinsic in origin may be the result of inflammatory disease, of trauma, of surgical procedures, or of radiation therapy.

In the light of recently acquired knowledge the most common cause of inflammatory rectal stricture is the virus of *venercal lymphogranuloma* (lymphogranuloma venereum). As the name implies this entity is venereal in origin—the sixth venereal disease according to Strannus.¹ Since the lymphatic drainage of the external genitalia is

inginal in either sex a primary lesion of the external genitalia in the male or the female is followed shortly by bubo formation. In the female however the primary lesion is likely to be established in the vagina or on the cervix. As a result the virus can invade the perirectal and rectal lymphatics either by way of the plexus of the rectovaginal septum or through the uterosacral ligaments (rectal stalks). In the male it is possible that the infection may travel along the urethra into the lymphatics of the prostate and thence to the rectal absorbents by way of the rectal stalks. In either sex infection may spread upward from an anal lesion through lymphatic vessels which connect the anal absorbent plexus with that of the rectum. Sodomy might result in direct implantation of the virus in the rectal mucosa. Lymphatic stasis in the presence of infection favors the growth of fibroblasts.¹ The fibrous tissue thus formed undergoes contraction. The resultant inflammatory stricture occurs usually in the lower half of the rectum. The Frei test is an established diagnostic procedure. Collier² & Martin³ has shown that there is no specific treatment thus far for this distressing condition. Surgical procedures are often necessary but the results are disappointing. In far advanced cases the best plan appears to be to establish a permanent colostomy and then to remove the rectum either by posterior resection or by a combined abdominoperineal operation.

ANORECTAL TUBERCULOSIS

Space does not permit a detailed account of the role of tuberculosis in anal fistula. Suffice it to state here that the incidence of tuberculous anal fistula is probably below 3 per cent and that modern regional anesthesia permits one to treat a tuberculous anal fistula exactly as outlined in the section on fistula in ano.

Anorectal tuberculosis is not common it is practically always secondary. Tuttle¹ states: "All tubercular processes of the superficial teguments arrive sooner or later at an ulcerative stage." Accordingly, therefore perianal or anal tuberculosis may be either simple ulcerative or lupoid. Both Tuttle² and Buie³ call attention to the minimal pain accompanying these lesions. In addition Buie refers to "lupoid" tuberculosis of the anal canal as "proliferative" comparing it with hyperplastic colonic tuberculosis and presents the record to date of a patient whom he has observed since 1921. This story is well worth reading.⁴ Rectal tuberculosis is either ulcerative or hyperplastic. Grossly, the specimen of hyperplastic disease resembles closely that of inflammatory rectal stricture due to the virus of venereal lymphogranuloma.

PROLAPSE

Tuttle¹ points out that the terms prolapsus and procidentia—meaning a falling down—are synonymous. Buie's modification of the Tuttle classification is both simple and logical. He divides the types of prolapse into those which are visible and those which are concealed. The visible prolapse may be partial (consisting only of rectal mucosa) or complete (involving all the layers of the rectal wall). In the first degree of complete rectal prolapse the wall of the anal canal is everted too so that there is no groove or sulcus surrounding the protruding mass of tissue. In complete prolapse of the second degree the anal structures retain their normal positions accordingly there exists a sulcus entirely surrounding the prolapsed gut. Concealed rectal prolapse (Tuttle's third degree of complete prolapse) is an intussusception of the upper portion of the rectum and rectosigmoid into the lower portion of the rectum.

Etiology—The chief underlying factor in the etiology of rectal prolapse is an alteration or defect in the supporting structures of the anorectum. The exciting causes in these cases are mechanical strain, disease and injury.

Diagnosis—Partial prolapse must be differentiated from hemorrhoidal prolapse. In many instances they are associated. The concentrically arranged ridges on the surface of a completely prolapsed rectum are characteristic features; there is a striking difference between these rings and the radially arranged grooves or sulci seen in hemorrhoidal prolapse. Whenever there is a history of prolapse and examination fails to disclose the deformity, the patient should be asked to strain on the toilet in order to demonstrate his trouble. The nature of the condition is usually rendered quite obvious. The chief diagnostic problem is that presented by concealed prolapse. Examination of the patient in the usual tip up position fails to disclose the trouble because the intussusception is usually reduced by such a position. It may be necessary to examine the patient while he is standing upright in order to visualize the deformity.

Treatment—In infants and young children presenting partial prolapse conservative methods are often successful. The patient should lie down to defecate and the buttocks should be firmly strapped together during intervals between defecations. In older patients with partial prolapse it may be possible to accomplish satisfactory results with linear cauterization or with injection treatment (preferably quinine and urea hydrochloride 5 per cent).

The reduction of a chronically recurrent prolapse—either partial or complete—is usually accomplished easily by the patient himself who has long since become adept at manual replacement of his deformity. In these instances the anal musculature lacks its usual tone and offers little or no resistance. Oddly enough this atony facilitates both the prolapse and its reduction. The author once asked his preceptor, Collier F. Martin, for an explanation of the patulous or semipatulous anal canal so frequently seen accompanying tumors and strictures of the rectum and rectal prolapse. Martin said he had no scientific explanation for this phe-

nomenon but remarked that a tumor or a stricture or a prolapse is akin to putting a finger on a fiddle string—it somehow alters the tone! Buie has frequently called attention to the existence of a patulous anal canal (which can be contracted at will) in some elderly patients in whom no etiologic factor can be found either locally or in the central nervous system. The author has seen three patients with complete prolapse who could reduce the prolapsed tissue without local manipulation. They were apparently able to create a negative intra-abdominal pressure; the prolapse was literally sucked in.

In acute prolapse resulting from sudden strain or from crushing injury the engorgement of the tissues may become so great that gangrene follows. Reduction in such instances is a difficult problem. If the rectal wall is so friable that perforation is likely to occur the safest procedure is an amputative operation with every precaution being taken against opening the peritoneal cavity and injuring the small bowel which may be present. If only the mucosa is damaged gently but firm attempts at reduction should be undertaken with the patient in the inverted position. If necessary relaxation of the anal canal can be accomplished by regional anesthesia. After successful replacement of the prolapsed gut it is well to confine the patient to bed until the supports of the anorectum have had opportunity to resume a normal state.

When partial prolapse fails to respond to conservative management an amputative operation such as that described by Buie² is indicated. If this procedure is carried out properly and if diligent postoperative care is provided the outcome should be satisfactory.

The treatment of complete prolapse is usually surgical, necessitating obliteration of the cul de sac via an abdominal approach. The Moschowitz operation³ or some modification of it is indicated. Such a procedure is much safer than any operation done from below—especially for complete prolapse of the second degree in which the protruding mass is likely to contain peritoneum and small bowel.

ANAL PRURITUS AND HEMORRHOIDS

ANAL PRURITUS

Anal pruritus is a common anorectal complaint. Literally the term means anal itching; however it is used loosely to include a group of symptoms of variable importance such as itching burning smarting pricking superficial pain moisture slight bleeding at the time of evacuation and vermiculation. The symptoms are variable and intermittent and are usually worse at night or whenever the patient is laboring under nervous tension. The surface of the perineum scrotum labia and gluteal regions may become involved. The dentate margin limits the disease proximally. Anal pruritus is more common among men than women; it usually occurs among young or middle-aged persons and affects especially so-called tense or nervous persons.

In typical cases the involved skin appears grayish pink redundant and moist and may or may not show excoriations and abrasions; the perianal hair is diminished in amount or absent. Occasionally the altered skin may appear diffusely reddened dry glossy and on palpation warmer than the surrounding skin. The last named condition apparently is a less commonly observed phase of the disease.

Acanthosis nigricans dermatitis medicamentosa eczema leukoplakia lichen planus and psoriasis are some of the diseases to be considered in the differential diagnosis.

A thorough anorectal examination and sympathetic evaluation of the symptoms are required in each case in order to disclose all clues to the exciting factors. Unwarranted fear of carcinoma as a result of the irritation will often cause patients to seek relief.

To facilitate consideration of the treatment of anal pruritus the disease is classified as primary or secondary. Secondary

anal pruritus is the result of another anorectal pathologic process which has produced maceration or irritation. Such a pathologic process usually is obvious if a thorough anorectal examination is accomplished and the removal or correction of the abnormality usually will give satisfactory and prompt relief of the pruritus.

Primary anal pruritus usually is considered as a specific disease but its etiology is extremely obscure and the disease probably is the result of a number of unrelated factors. Local causes such as hemorrhoids cryptitis proctitis enlarged papillae and fungal or streptococcal infection occasionally cause this type of pruritus and efforts to eradicate them may produce temporary relief which is optimistically mistaken for a cure.

Treatment.—Any abnormality of physiologic function should be corrected if possible. It is frequently necessary to treat local dermatitis caused by previous therapeutic efforts before attempting curative measures. Washing the involved region with mild soap and cold water and the bare hand usually will help and this measure may be followed by the application of a small amount of ointment which contains tar menthol camphor or phenol or a pledget of cotton saturated with undiluted witch hazel may be applied. A cold pack of gauze saturated with witch hazel or a 0.5 per cent aqueous solution of aluminum subacetate may be applied in the more severe cases. Calamine lotion also will aid in some cases as will 5 per cent ichthylol or 3 per cent ammoniated mercury ointment in a zinc oxide ointment base. It is advisable to prescribe several types of applications and advise alternating their use because although temporarily efficacious any one agent tends to become ineffective if used constantly.

Technic of Injection of Alcohol.—Subcutaneous injection of 20 to 40 cc of a 40 per cent solution of ethyl alcohol will produce a satisfactory result in about 87 per cent of the cases in which it is properly employed.¹ Sacral or low spinal anesthesia is desirable. A 21 gauge needle 80 mm long and a 10 cc Lundy syringe are used to inject the solution. The needle is introduced in the midline 2 to 4 cm posterior to the anus and guided subcutaneously along the right side

of the anus to the anterior edge of the field to be injected. The solution of alcohol is then injected as the needle is withdrawn special care is exercised to introduce the solution proximally as far as the dentate margin and under all of the radial folds of the perianal skin. The process is then repeated on the left side of the anus and if necessary the needle may be introduced anteriorly in order to complete the injection. The injection must be confined to the region covered by the freely movable perianal skin. The injection is painless. Cold packs should be applied for from four to eight hours daily until the slough which frequently occurs is localized or removed after this hot wet packs assist materially. Close observation and intelligent care of the wounds are imperative as such wounds are always infected. If sloughing occurs the patient may have an elevated temperature and may complain of headache, anorexia and generalized aching for several days.

Tattooing with mercury sulfide has been advised and seems to produce encouraging results.

HEMORRHOIDS

Thrombosed External Hemorrhoids.—Firm tender painful bluish localized swellings which suddenly appear at the anal margin frequently after abnormal function of the bowel or strenuous work usually are thrombosed external hemorrhoids. They occur as subcutaneous extravasations of blood or thrombi occurring within dilated varices. These lesions may be multiple and their occurrence is not irrefutable proof of the presence of internal and external hemorrhoids. Unless the thrombus is recognized and surgical measures are instituted promptly such treatment is of doubtful value because it will not abbreviate the period of discomfort nor will it prevent recurrence.

If not treated promptly these lesions cause pain for from three to seven days after which they gradually subside during the ensuing three to five weeks and the discomfort diminishes irregularly. A small residual tag of skin may be noted.

For the purpose of treating these lesions they may be divided arbitrarily into three types.

Type 1—If the thrombus is attached to the overlying skin as indicated by the presence of localized discoloration at the apex of the swelling a painless incision may be made in the adherent region with a sharp scalpel and the thrombus expressed. The resulting cavity may fill with another blood clot but this will be less painful than the original thrombus. Local cleanliness obtained with soap and water will prevent infection.

Type 2—When the thrombus is covered by freely movable skin it may be removed by encircling the involved region by an injection of 1 per cent solution of procaine hydrochloride and the clot evacuated or removed through a radially situated elliptical incision. One or more sutures may be required for hemostasis.

Type 3—Internal and external hemorrhoids may become hosts to innumerable tiny thrombi and edema subsequent to an unusual straining or strenuous activity. The resultant swelling may be sufficiently severe to cause protrusion of mucous membrane and sloughing of the involved skin and mucosa may occur because of constriction of the anal sphincter injury and infection. When the protruding tissue is first encountered one is tempted to replace it if this is accomplished gently the effort is not unwise. However such an effort more frequently will cause increased pain and swelling. The application of hot wet packs for from four to eight hours daily the prevention of straining and the employment of sedatives will help to provide comfort and the reasonably prompt absorption of the thrombi and edema. After the swelling has nearly subsided hemorrhoidectomy may be performed without added risk.

Marginal Varicosities.—Occasionally a patient will complain of protruding hemorrhoids which require digital replacement but examination will fail to disclose hemorrhoids of sufficient size to cause such symptoms. If the patient assumes a sitting or squatting position and is asked to strain it will be discovered that the protrusion is a swelling of the perianal region caused by subcutaneous varices or external hemorrhoids and that instead of replacing a protruding mass the patient evacuates the blood from the varices by digital pressure.

These masses frequently are called marginal varicosities. Treatment consists of surgical excision.

Internal and External Hemorrhoids—Internal and external hemorrhoids are soft tumors occurring at the anus as a result of the presence of superficial varices. They are irregular in size, shape and distribution. Hemorrhoids covered with mucous membrane are called internal hemorrhoids and those covered by skin are called external hemorrhoids.

Although a lengthy list of etiologic and irritating factors might be provided, it is difficult or impossible to ascertain the exact cause in any given case. Frequently an irritating factor is so apparent that it assumes a dominant position in attempts to determine the causative factors. Present knowledge of the etiology of hemorrhoids is of such slight practical value that our preventive efforts are only palliative.

The symptoms caused by hemorrhoids are numerous; they vary in intensity and occur in all possible combinations. To mention a few symptoms may be of aid: bleeding, pain, protrusion with eversion or physical strain in which the protrusion may reduce itself spontaneously or require digital replacement, secondary anemia with its associated symptoms and alteration of intestinal function attributable to discomfort or irritation etc. Hemorrhoids are blamed for many distant discomforts but often they are unrelated or coincidental.

The diagnosis of hemorrhoids cannot be determined by either the history or digital examination alone. A carefully obtained history, a thoughtful evaluation of symptoms and a thorough proctosigmoidoscopic examination are necessary. Nearly all lesions which occur in the anorectal region cause symptoms which are so similar that only with constant intelligent curiosity and a knowledge of anorectal pathology can embarrassing errors be avoided.

Treatment—The treatment of hemorrhoids can be divided into three types, namely: (1) palliative, (2) non surgical and (3) surgical. Palliative treatment consists of ingeniously providing sufficient comfort to permit postponement of the application of curative measures. Palliative measures may include avoiding heavy labor, applica-

tion of hot wet packs after defecation and administration of medicinal agents such as mineral oil in order to insure a soft stool and the control of diarrhea or other abnormal function of the bowel.

The non surgical type of treatment includes all methods which do not require intentional removal of hemorrhoidal tissue. The injection of chemical solutions into the hemorrhoid in order to produce a sterile inflammatory reaction and the application of electric energy in one of its various forms in order to produce inflammation or actual destruction of tissue are the non surgical methods most frequently employed.

Treatment by injection is used more commonly than electrolysis or electrocoagulation. Numerous solutions have been suggested but 5 per cent aqueous solution of quinine and urea hydrochloride and phenol in vegetable oil are the solutions most commonly used at present. The 5 per cent aqueous solution of quinine and urea hydrochloride prepared for injection into internal hemorrhoids may be obtained from most pharmaceutical houses. This solution insures a greater margin of safety than most of the other solutions. Injections may be repeated more promptly if necessary, a satisfactory inflammatory reaction is obtained and the solution does not produce permanent palpable scarred nodules.

Small or moderately large internal hemorrhoids uncomplicated by thrombi, edema, protrusion or infection may be treated by this method. A 5 cc glass syringe in which a small-caliber needle 10 cm long is attached can be used for the injection of quinine and urea hydrochloride solution and a tuberculin syringe to which a tonsil needle is attached may be used for the injection of phenol and vegetable oil solution. The hemorrhoid is exposed by means of a Hirschman anoscope; the patient is placed in a semi-inverted knee-chest or left Sims position. A point 0.5 to 1 cm above the dentate margin is selected for insertion of the needle and the surface of the hemorrhoid is cleansed with a mild antiseptic solution. The needle is inserted for a distance of 0.3 to 0.5 cm and should be freely movable. The amount of solution injected varies with each hemorrhoid. After the injection of quinine and urea hydrochloride solution is com-

pleted the hemorrhoid should appear distended but not blanched. If phenol and vegetable oil solution is injected 0.12 to 0.6 cc (2 to 10 mmms) is sufficient. It is advisable to inject too little solution rather than too much. Twisting the needle before withdrawing it will prevent leakage or loss of solution. One or more hemorrhoids may be injected at one time depending on their size and location and on the patient's reaction.

The injection may cause pain. This usually occurs promptly and persists for several hours but may respond to rest and the administration of acetaminophen or codeine sulfate. The injected tissue should be observed at least every other day until the inflammatory process has subsided and the physician should require prompt notification if bleeding or protrusion occurs. The injection may be repeated as soon as the acute phase of the inflammatory process has subsided. Sloughing or other complications occurring after non-surgical treatment deserve special care because the wounds are infected. Rest in bed, hot irrigations, hot wet packs, a non-residue diet and sedatives are measures which may be employed in the care of such complications.

Surgical excision of internal and external hemorrhoids provides an unusual opportunity for practical application of the knowledge of anorectal anatomy, pathology of hemorrhoids and the principles of plastic surgery. In general it is best to be as radical as necessary but as conservative as possible. No one particular operation pursued step by step will cure all hemorrhoids. A basic operation which lends itself to alteration will be described presently.

The patient is admitted to the hospital the evening prior to operation or if the operation is to be performed in the afternoon he is admitted in the morning of the day of operation. He should not eat breakfast however. Several enemas of soapuds or saline solution administered through an 18 F catheter instead of a hard rubber enema tip will provide a field sufficiently clean and free from unnecessary trauma or irritation. Sedatives and other preoperative medication will vary with the type of anesthesia to be employed. Several types of anesthesia can be used in order of value with regard to their safety and the resultant re-

laxation and lack of distortion they are as follows: sacral low spinal infiltration and general or inhalation.

The best exposure of the operative field is obtained by placing the patient prone with the hips slightly elevated by means of a padded kidney rest or transverse bar. The surgeon and the second assistant operate from the patient's left side and the first assistant operates from the patient's right. After anesthesia has been induced the shaved skin of the perianal gluteal, sacrococcygeal and perineal regions is treated with an antiseptic solution such as tincture of metaphen and a handful of stuffed gauze is placed over the perineum.

Careful digital examination is performed in order to detect any abnormalities which may have escaped previous notice. If anal contraction is discovered the anus is dilated gently to admit two fingers. A large Hirschman anocope is then inserted into the anus, the obturator is withdrawn and after the removal of any feces, mucus or water that may be present a gauze sponge is placed in the rectum by means of an 8 inch (20 cm) dressing forceps. Three gauze sponges are then introduced through the anocope by means of the dressing forceps and the anoscope is removed over the forceps while the grasp on the sponge is maintained. After the anoscope is withdrawn the gauze sponges are slowly pulled outward partially through the anus. The bulk of the gauze should be sufficient to obstruct the venous flow and thereby to cause distention of the internal and external hemorrhoids. The operation is actually planned as this distention reaches its maximum. With the hemorrhoids distended it usually can be decided whether to take them out in four, three or two groups by the amputation of one side by the amputation of the entire circumference of the anus by dividing it into right and left halves or by complete amputation of the anal circumference (a cuff). The decision depends on the surgeon's judgment and experience.

The surgical objective is to remove the hemorrhoids and to restore the relationship of the mucous membrane and skin so that when healing is complete distortion will not result. The fibers of the external sphincter provide an unusual landmark for the ex-

ternal hemorrhoid is removed so that the muscle is exposed and forms the base of the wound the surgeon can be certain that he has removed all of it. Also if the edge of the wound in the mucosa resulting from the excision of the internal hemorrhoid is drawn outward and sutured circumferentially to the inner fibers of the sphincter the normal relationship of skin and mucous membrane will be reestablished after healing is complete.

To remove a comparatively small internal-external hemorrhoid a 6¼ inch (16 cm) Mayo-Ochsner clamp is placed in the normal skin at the lateral extremity of the ex-

ternal hemorrhoid. Dissection is started laterally between the tenaculum and the lateral clamp and is continued medially to between the medial clamp and the ligature. If as the dissection is started the surgeon makes sure that the fibers of the sphincter form the base of the wound that he is producing the dissection usually progresses easily.

After excision is completed the mucosal stump encircled by the ligature is drawn outward to the level of the proximal fibers of the external sphincter and two half Lambert sutures one on either side of the stump are passed first through the mucosa and then through a few of the fibers of the ex-

Fig 581 Steps in the removal of internal and external hemorrhoids. *a* clamps 1, 2 and 3 in place over marked *b* dissection begun *c* dissection completed half Lambert suture on one side begun, *d* mucosa retracted other half Lambert suture begun *e* operation completed (Gauze in *b*, *c*, *d* and *e* for illustrative purposes only)

ternal hemorrhoid and another similar clamp 0.5 to 1 cm above the internal hemorrhoid (Fig 584 *a*). A tenaculum is then placed lateral to the first clamp and sufficiently deep so that it may be employed as a retractor. The three gauze sponges are then removed from the anus and with a no. 3 Mayo taper point curved needle a double tie of no. 1 plain catgut is placed internal to the clamp (Fig 584 *b*) in the normal mucous membrane. The suture is tied so that there is one long end. The tenaculum and the suture provide the means of retracting and fixing the tissue to be removed (Fig 584 *b*) and the Mayo-Ochsner clamps are employed to manipulate the hemorrhoidal tissue as it

is being removed. Dissection is started laterally between the tenaculum and the lateral clamp and is continued medially to between the medial clamp and the ligature. If the sutures are properly employed the mucosal stump and the adjacent margins of the wound in the mucous membrane will be situated at the level of the inner fibers of the external sphincter (Fig 584 *d* and *e*). It may be necessary to insert one or two sutures for hemostasis. After one hemorrhoid is removed three more gauze sponges are inserted into the rectum and the process is repeated or adjusted to provide for the satisfactory removal of the other hemorrhoids or associated pathologic processes.

The technique as outlined may be varied greatly especially if the surgeon will notice that an irregularly diamond shaped wound

is produced when the excision is completed. The two medial sides in the mucosa may be retracted and so sutured that the diamond may be altered to produce a triangular wound with the elongated base of the triangle formed by the mucosal edge sutured to the internal fibers of the external sphincter. The other two sides of the triangle will be formed by the cutaneous margins of the wound. Several clamps can be used in the mucosa to mark the internal limit of the excision and to provide traction or hemostasis. Several more clamps can be used in the skin to provide easy manipulation of larger hemorrhoidal masses. The first double tie can be placed so that the mucosal stump will be posterior to the midpoint of the incision in the mucosa and the resulting mucosal edge can be sutured to the internal fibers of the external sphincter by means of a continuous locked suture using the long end of the tied suture. If clamps are used to mark the internal limit of the region to be excised then before the dissection is started the suture may be placed posterior to the margin of the hemorrhoid sufficiently deep so as to catch the fibers of the external sphincter. The suture is tied with a long end. This procedure will insure more accurate placement and will expedite suturing since this much will be accomplished before bleeding occurs. If clamps are used dissection may be completed and the mucosal edge retracted and sutured to the internal fibers of the external sphincter by interrupted half Lambert sutures.

At the time that the mucosal edge is sutured to the sphincter two factors must be observed closely. 1. The mucosa must not be drawn too far outward for an ectropion of mucous membrane will result. 2. The mucosal edge must not be sutured to the internal edge of a partially everted external sphincter for if this is done then after normal muscle tone returns an overhanging edge or shelf will be produced which may cause an abscess during convalescence. Both of these errors can be avoided by close observation. It is important also that sufficient skin be removed to permit ample drainage of the wound.

Postoperative Care.—The care of the patient and the wounds after operation is important. At the completion of the opera-

tion a soft gutta percha drain 3 or 4 inches (8 or 10 cm) long is inserted into the anus on both sides of this drain several strips of 2 inch (5 cm) petrolatum gauze are placed which are removed in from eighteen to forty eight hours. After the patient has returned to his room his pulse rate should be observed every half hour for eight hours. A sixth to a quarter grain (0.01 to 0.16 Gm) of morphine sulfate is administered hypodermically as required until the acute pain has subsided. As soon as the anesthesia has disappeared either hot or cold moist packs may be applied. The postoperative perianal injection of solutions producing prolonged anesthesia frequently causes rather specific results but the method is not free from risk.

The patient may experience difficulty in voiding but if assisted he may be permitted to stand beside his bed or even go to the bathroom. All efforts should be exercised to obtain normal daily stools. The diet may be altered if necessary but about five to seven days will be required to establish this regulation. After each evacuation the anus and wounds should be irrigated with warm water (approximately 110° F) by means of an 18 F catheter attached to an enema bag. Hot, moist packs should be applied for from four to six hours daily until most of the soreness has subsided. The patient may be permitted to be up for increasing periods after forty eight hours has elapsed postoperatively. It is advisable for the patient to stay in the hospital until the sutures have been absorbed or removed. Bleeding tends to occur most frequently from the eighth to the tenth day after operation. The wounds should be closely examined daily for any abnormalities. Irrigate with witch hazel and treat with a non irritating anti septic such as an aqueous solution of metaphen. Alert observation to detect complications promptly and to care for each patient's problems sympathetically will be repaid by sincere gratitude and appreciation.

CARCINOMA OF THE RECTUM AND ANAL CANAL

Whether carcinoma of the rectum is becoming more prevalent or the clinician is becoming more skillful in the use of modern means of diagnosis is a matter of speculation but certainly the disease is being recognized more frequently than ever before. Next to the stomach the rectum is the most common site in the gastrointestinal tract for malignant disease. In 34th cases of malig-

Fig. 58a.—Resected specimen of the rectum and sigmoid. A and B Adenocarcinoma grade 4. C and D polyps involved in an adenocarcinoma grade 4.

nancy of the large intestine in which operation was performed at the Mayo Clinic from 1907 through 1928 9259 or 63.48 per cent of the lesions occurred in the anus, rectum and rectosigmoid. This high incidence in the rectum should impress the clinician and surgeon of their grave respon-

sibility in requiring a full knowledge of the characteristics of this disease so that they can make earlier diagnoses and promptly institute suitable treatment. In too many instances the patient has been subjected to hemorrhoidectomy after the onset of symptoms of carcinoma. This occurred in 98 per cent of a large group of cases observed by the writers.

Men are affected more commonly than women in the ratio of about three to two. In the writers series of cases the average age was fifty-seven years; most of the patients were between forty and seventy years of age. However, young persons often have the disease. Rankin and Comfort reported that the incidence of carcinoma of the rectum of persons aged thirty or less in a series of over 2000 cases was 3.85 per cent. Cancer of the different parts of the digestive tract in the young has been exhaustively reviewed by Jordan and Chamberlain.

Etiology.—Surmises as to the etiological factors involved in the production of carcinoma are perhaps frequently unwise or ill timed but unquestionably it is possible to trace certain frequently found lesions in the rectum and large bowel through the different stages of their malignant metamorphosis (Fig. 58a). This is particularly referable to the changes which are seen in multiple or single polyps which are so frequently found in an otherwise normal bowel. This subject is considered in greater detail in the chapter on carcinoma of the colon.

It is the opinion of Fwing Pennington Jones and the writers that carcinoma of the rectum does not develop as a result of benign lesions such as anal fissure, ulcerative proctitis, hemorrhoids and strictures. Rosser on the other hand considers that these lesions are precursors of carcinoma. Constipation as an etiologic factor is of little significance. Pennington made the pertinent observation that constipation is notoriously more common in women yet the incidence of carcinoma of the rectum in this sex is less than in men and as DuPan has pointed out the anus which is the portion of the rectum most liable to become irritated by the passage of feces is the most infrequent site of carcinoma.

Pathology.—There is considerable controversy among proctologists as to the fre-

quency with which carcinoma occurs in the various segments of the rectum. The writers believe that most carcinomas of the rectum are at the rectosigmoid juncture that the next point of frequency is in the ampulla of the rectum and that the site of least frequency is the anal canal and the lower 5 to 7 cm. of the rectum. Growths at the rectosigmoid juncture have a tendency in many instances to prolapse into the ampullary portion of the rectum and in this manner mislead the proctologist in determining the true location of the growth. The anterior and posterior walls appear to be more often affected than the lateral wall.

The usual type of growth, excluding the anal canal is an adenocarcinoma. Various classifications have been given to carcinoma of the rectum, some based on clinical ground, others on histologic grounds and still others representing a combination of both. All carcinomas of the rectum however develop from crypts or glands of Lieberkuhn and those originating in the anal canal are true squamous cell carcinomas. Of considerably more significance than the classification of carcinoma of the rectum on clinical grounds or according to physical attributes of the invading growth is a microscope grading of the neoplasm on the basis of cell differentiation as has been described by Broders. In a study of 2000 epitheliomas 1628 of which were of the squamous cell type Broders classified them into four groups according to differentiation and mitosis. The more nearly the cell approaches the embryonic or undifferentiated type the more malignant the tumor and conversely the more nearly normal the tumor cell the lower the grade of malignancy. The grading was made on a basis of 1 to 4 and entirely independent of the clinical history. This work was substantiated by Martzloff in 1923 by Greenough in 1925 and by Dukes and Gabriel in England and many others in this country.

Approximately 5 per cent of carcinomas of the rectum are of the mucoid or colloid type. A detailed consideration of this type of carcinoma may be found in the section on the colon. Epitheliomas originate in the anal epidermis and are in most instances highly malignant. Such growths are comparatively rare. Metastasis occurs early and

by the way of the inguinal nodes rather than upward toward the retroperitoneal nodes as is the case when the growth is situated above the anal canal.

Three methods of extension through the lymphatics are described by Miles: (1) downward into the wall of the bowel below the growth into the rectal sphincter and ischiorectal fossa; (2) laterally into the fascia propria, levator ani muscles, capsule of the prostate gland, seminal vesicles and base of the bladder in the male and the vaginal wall and genitalia in the female; or (3)

Fig. 586.—Extramural lymphatic lines of the rectum and sigmoid. (After Miles from Rankin, Hargen and Day.)

upward into the bowel above the growth and the pelvic peritoneum and mesocolon (Fig. 586). If remote metastasis occurs the liver is usually affected first. Rectal carcinoma may reach this organ through glandular metastasis or by the breaking off of emboli of carcinoma cells into the portal circulation. McVay, Rankin and Olson, Gabriel, Dukes and Bussey, and Gilchrist and David have shown that the size of the growth in the rectum cannot be relied on as an accurate index to the probable lymphatic involvement and that the growths without

lymphatic involvement tend to grow into the lumen of the bowel

Symptoms—Renal complaints are notably undependable symptoms produced by carcinoma of the rectum or colon will often be found to vary widely in different cases and any of them may be produced by other rectal or intestinal disorders. Unfortunately early diagnosis cannot be made from any definite line of symptoms and the symptoms which may be considered as suggestive are not uniform but occur in enough instances to stress the importance of making an examination if there is any evidence of irregularity of bowel habits. The alertness of the clinician in urging this type of examination and referring the patient for treatment will increase the good results of removal by allowing treatment to be undertaken at a less advanced stage of the disease. Commonly symptoms have persisted for a considerable time before the patient comes to operation. The average duration of symptoms in cases of carcinoma of the rectum is approximately eleven months.

Unquestionably the most frequently encountered symptoms and signs of carcinoma of the rectum none of which is pathognomonic or distinctive are bleeding, irregularity of stool and pain in the order named.

Bleeding—The most constant sign of a malignant condition of the rectum in the writer's experience has been bright blood which in some cases was mixed with the stool and in others simply streaked the stool. Moreover it is probably one of the earliest manifestations of carcinoma of the rectum. Of 1937 patients with carcinoma of the rectum and sigmoid treated in the Mayo Clinic from 1910 to 1922 there was a history of bleeding in 84 per cent. The average hemoglobin value however was 72 per cent showing that anemia with carcinoma of the rectum except when the disease is far advanced and metastasis has occurred is not as common as it is with carcinoma of the right segment of the colon.

Irregularity of the Habit of Going to Stool—Change of bowel habit or irregularity of the large bowel however slight if it persists should indicate the necessity for a thorough examination of the gastrointestinal tract. In a series of 539 cases reported

by Rankin constipation was the predominant complaint in 332 cases (55 per cent) and in 20 per cent diarrhea was the most prominent manifestation. The diarrhea varied from that indicating a mild irritability of the bowel evidence of which was elicited only on close questioning to the passage of eight or ten stools daily. Usually the diarrhea does not alarm the patient until dehydration or weakness from the loss of fluid is apparent. In the cases in which constipation was the predominant symptom marked variation was observed in its description; some patients considered constipation as it is usually conceived as a normal state and realized that obstruction was present only when the use of drastic purgatives failed to bring relief or when associated signs and symptoms such as pain or blood in the stool developed.

Pain—Pain is an untrustworthy symptom present in some cases absent in others excessive at times or of moderate severity. It has little if any relation to the presence of the growth until the neoplasm has extended beyond its local confines or has fastened itself to some viscus or nerve trunk where its irritation constantly calls attention to its presence. Because the rectum is not endowed with pain sensation the physician is deprived of one of the most valuable aids in identifying a malignant lesion of the rectum in its earliest stages.

Excessive loss of weight or strength—Symptoms which are so frequently recorded in textbooks as indicative of carcinoma of the rectum are worthless in the early recognition of the condition since they indicate metastasis to distant organs in most cases. Loss of weight is not usually appreciable until late in the course of the disease. In fact most patients are in such apparent good health in spite of a long history and advanced lesions that one might think of the robust person as the type subject to neoplasia of the rectum.

Involvement of adjacent organs and structures—such as the prostate gland, vagina, urinary bladder, uterus or sacrum produces symptoms referable to disease of those structures and secondary infection in perirectal growth not infrequently leads to ischio-rectal abscesses and fistulas.

Diagnosis—Digital examination although important should never be considered conclusive. Many of the lesions which involve the rectum, rectosigmoid and sigmoid flexure are above the reach of the index finger during the ordinary digital examination and the only satisfactory way to search for these pathologic conditions is by the visual method using the proctoscope and sigmoidoscope.

The appearance of carcinoma of the rectum, rectosigmoid or sigmoid flexure is so characteristic that it should rarely be confusing even to those who have had relatively little experience in making proctoscopic examinations. Such lesions once seen should not and hardly can be forgotten. In the first place any single lesion whether an excavating ulcer or a proliferating mass should be regarded with suspicion. The fact that the lesion is single is in itself almost pathognomonic of carcinoma since almost any other lesion encountered there will be associated with some inflammatory reaction and when inflammation and infection are present a single lesion is rarely found. It is a peculiar characteristic of carcinoma that adjacent tissues appear unusually normal. Polypoid growths may possess all the characteristics mentioned but they should always be considered to be potentially malignant (Fig 585).

Since a lesion which is operable from every point of view must be considered inoperable at times because of its excessively malignant cellular structure specimens should be taken as a routine procedure or if not routinely certainly when there is doubt as to the true nature of a lesion. It should be remembered that a positive report on microscopic examination is conclusive but a negative report is not for it may mean that the specimen was not taken deeply enough or from the proper place and a second section may prove the error.

Treatment—Usually operation is considered the treatment of election in most cases of operable carcinoma of the rectum, rectosigmoid and anus. For lesions of the anus alone an appreciable number of surgeons will choose treatment by irradiation in preference to operative measures particularly for epitheliomas grades 3 and 4.

Operability and Prognosis—Operability implies the consideration of all conditions favorable and unfavorable to the removal of carcinomatous growths conditions which in borderline cases must be measured and evaluated according to the judgment, experience and courage of the surgeon. The standard of operability has gradually improved with the refinement of surgical technique and the development of greater skill by individual surgeons. Operability and prognosis have been determined by such modifying influences as age, sex, obesity, general health, duration of the lesion with its attendant signs and symptoms and various local conditions associated with the neoplasm such as size, situation and mobility, the relative malignancy and the presence or absence of metastasis both lymphatic and visceral. A detailed consideration of these factors which apply equally to the colon and rectum may be found in the section on Carcinoma of the Colon.

The index of malignancy applied to biopsy obtained from rectal neoplasms is of value in judging inoperability in certain cases. Rankin and Broders have shown that the grade of the malignancy has a direct bearing on the percentage of metastasis and absence of metastasis since the percentage of patients with metastasis increases in proportion to the grade and the percentage of patients without metastasis increases in inverse proportion to it. The following analysis of 853 cases of cancer of the large bowel strikingly demonstrates that the degree of malignancy materially affects the prognosis.

CANCER OF THE LARGE BOWEL

		Grade 1	Grade 2	Grade 3	Grade 4
With glandular involvement (397 cases)					
Incidence		9%	31%	28	12%
Five year cures		41%	34%	15%	15%
Without glandular involvement (466 cases)					
Incidence		10%	60%	16%	6%
Five year cures		69%	56%	40%	37%

In 1937 Dukes of St Mark's Hospital (London) reported that he had graded 600 cases of cancer of the rectum and had reached the conclusion that if tumors are graded by Broders' method the after history will show that there is a distinct difference in the survival rate according to the grade. A study of 200 cases graded more than five years previously revealed the following death rates from metastasis: 40 per cent for grade 1, 56 per cent for grade 2, 76 per cent for grade 3 and 100 per cent for grade 4.

Gilchrist and David reached the following conclusions from an analysis of the specimens studied in their series. The size of the tumor is of little value in determining the presence or absence of lymph node metastasis. Low lying tumors may have metastasis very high. If the upward lymph channels are blocked by metastasis there may be a retrograde metastasis downward. When the tumor is found at the level of the levator ani muscle the lymphatic drainage may be lateral as well as upward. Similarly squamous cell carcinomas which involve the mucosa have a double lymphatic drainage consequently a radical resection of the rectum is indicated when this occurs. Tumors having lymph node metastases tend to be of a higher classification according to Broders grading than those without metastases. Finally they concluded on the basis of the foregoing findings that radical removal of the rectum and distal end of the sigmoid with resection of the superior hemorrhoidal artery as high as possible and wide resection of the levator ani muscles is necessary in order to give the best chance of permanent cure. The Miles type of operation in their opinion has fulfilled these requirements.

The operability and prognosis also depend on the presence and extent of lymphatic metastasis. Extensive investigations along these lines reported by Gabriel Dukes and Bussey (1933) and Gilchrist and David (1935) have been highly illuminating. Grossly the appearance of a lymph node may be entirely normal and yet microscopic section will reveal a malignant growth. On the other hand large lymphatic structures which are hard to touch and give an impression of malignant tissue are frequently

found to be inflammatory. Gabriel Dukes and Bussey reported that in a series of 1242 nodes removed from peritumoral specimens 905 were considered from gross appearance to be free from metastasis yet microscopic study showed that 18 were cancerous in error of 2 per cent. On the other hand of 337 nodes which were thought from their gross characteristics to be cancerous metastasis was present actually in only 192. Gilchrist and David in a similar study of 496 nodes reported that of the 111 lymph nodes containing carcinoma only 48 showed any gross change even in cross section of the gland. Their study further revealed that 68 per cent of their operatively removed specimens of carcinoma of the rectum showed metastasis to lymph nodes.

Until more adequate therapeutic agents than operation offer greater opportunities for cure or palliation to sufferers from carcinoma radical extirpation undoubtedly is justified in all cases up to and frequently including those of borderline operability. Certainly only a little is lost and perhaps much is gained if a questionable growth is extirpated.

Choice of Operation.—It is difficult to make a dogmatic choice of an operation for carcinoma of the rectum. It is not probable that any one procedure will ever be applicable to all types of carcinoma of the rectum and rectosigmoid for the reason that patients present themselves at such varying stages of the disease and consequently in such different physical states as regards both metastasis and local extension of the growth and because the lymphatic drainage from different divisions of the terminal bowel is by widely divergent channels. Therefore any surgeon who operates on patients with carcinoma of the rectum should have at his command a number of procedures and should make the selection that seems wisest in each case for example colostomy and perineal extension abdominoperineal resection in one stage abdominoperineal resection in two stages and palliative operations such as colostomy and local cauterization. The employment of one operation to the exclusion of all others decidedly narrows the scope of usefulness which surgical treatment offers to these sufferers and unquestionably vitally influences the immediate mortality.

the functional results and the ultimate survival.

The following analysis of the experience of one of us (Rankin) shows the variety of procedures employed and the tendency toward more frequent performance of the radical abdominoperineal operation of Miles.

CANCER OF THE RECTUM AND RECTOSIGMOID

	Cases	Deaths

Colostomy with perineal excision has had its greatest popularity in England and America is practiced to a less extent in France and is hardly ever practiced in central Europe. Miles abandoned this method of procedure in favor of the more radical combined abdominoperineal operation which bears his name. Lockhart Mummery on the other hand prefers perineal excision to all other methods and contends that the actual difference between the amount of tissue removed by this operation and by the abdominoperineal route is so slight as to make no difference as regards recurrence provided the lesion is situated below the rectosigmoid junction. This however has not been the opinion of the majority of those who have had considerable experience with the surgical treatment of carcinoma of the rectum. Distinctly, it has not been the writers' opinion.

In order to avoid the objections to many of the proposed operative procedures and to preserve the desirable features of the single stage operation various two stage procedures based on the abdominoperineal principle have been devised. These including the perineoabdominal resection of Rankin and a similar procedure of Tahey have in the opinion of the writers a very limited applicability. As one's experience with the Miles procedure increases the tendency to resort

to the less satisfactory two stage operations decidedly diminishes.

Along with an overwhelming majority of those surgeons both in this country and England who are particularly interested in the treatment of carcinoma of the rectum we feel that the occasional success which attends interior resection of the rectosigmoid with restoration of bowel continuity does not counterbalance the greatly increased morbidity and recurrence mortality as contrasted with adoption of permanent colostomy in all but highly selected cases.

Sacral operations have rarely been employed in this country or in England in the last decade but on the continent particularly in Germany and Austria the sacral route has been used almost to the complete exclusion of all other maneuvers. The operative and the recurrent mortality together with the percentages of poor functional results have been excessively high.

Colostomy is regarded as of the greatest value as a palliative procedure. However there is some difference of opinion in regard to the employment of colostomy for inoperable carcinomas of the rectum. At present however there are few surgeons who are unalterably opposed to colostomy as a palliative procedure. Its urgent need in the presence of complete obstruction is universally conceded its justification previous to this stage is challenged by a few. Since in most instances operability is not determined until the abdomen has been explored it would appear that the logical time for establishing colostomy would be at the initial operation when inoperability is determined. The absence of obstructive symptoms is of little significance and rarely should influence postponement of colostomy since in most instances some degree of obstruction will eventually develop. In the event that the obstruction is acute owing to a sudden blockage of the lumen in instances of unusual lesions and unrelieved by medical measures blind cecostomy rather than colostomy is indicated. A detailed consideration of decompressive measures may be found in the section on carcinoma of the colon.

The status of radium and roentgen rays in cases of carcinoma of the rectum is not well defined. Many who have had consider-

able experience with irradiation consider that it must be regarded as being still in the experimental stage. Certainly one can expect little more than palliation when roentgen therapy is employed for rectal carcinoma.

Operative Procedures—The acceptance of the postulate that all carcinomas that can be extirpated should be dealt with radically, not alone by their removal but by removal of the contiguous gland-bearing tissues as

neum are removed. All subsequent surgical developments in this direction have been based on the principles of the Miles operation.

Miles Operation—Through a low midline incision the abdomen is opened and after exploration of the liver and lymphatic structures for metastasis the sigmoid flexure is isolated. The peritoneum is incised on both sides of the bowel and in front of the bladder in order to insure adequate mobilization

Fig. 387—Abdominal operation for carcinoma of rectum (Miles) employing Cope clamp. Crushing force is applied to the distal end of the bowel segment until each is locked by a special catch. After removal of the crusher the middle segment of the clamps is unlocked and removed and the exposed thin lamella of crushed bowel is sealed by the cautery (Insert).*

well predetermines a formidable procedure in dealing with carcinoma in this region. The lymphatic drainage involved in carcinomas of the rectum that are above the anal canal has been excellently worked out by Miles, who in addition to these pathologic studies has contributed to the technical perfection of a radical combined abdominal-perineal procedure in which the growth and all the regional nodes of the pelvic floor and peri-

neum are removed. All subsequent surgical developments in this direction have been based on the principles of the Miles operation. The sigmoid is further freed by blunt dissection into the hollow of the sacrum. All tissues including fat and lymphatic vessels in this region and on both sides of the bowel up to the base of the inferior mesenteric vessels are freed by blunt dissection. The bowel is then divided between clamps at a point where the blood supply is adequate

*Rankin and Graham: Cancer of the Colon and Rectum. Charles C. Thomas, Publisher.

and the proximal end is delivered through a small left inguinal wound to form a single barreled colostomy the distal end is inverted and dropped into the pelvic cavity, after which a new pelvic floor is formed by approximation of the lateral peritoneal flaps. The abdomen is closed without drainage.

The resection in our opinion is facilitated by the employment of the Cope clamp (Fig 587) which simplifies division of the bowel particularly when there is present considerable adipose tissue and obviates the necessity of inverting the distal end of the sig-

operation described here allows one to perform a radical operation when the patient's condition is so debilitated and undermined that a single stage operation would be attended by a prohibitive mortality and the only other choice would be a colostomy and subsequent posterior resection. It is particularly applicable in the less sturdy risks when the growth is situated at the rectosigmoid. In our opinion however neither this procedure nor Lahey's modification of it should be employed if appraisal of the patient's condition would seem to warrant the

Fig 588—Abdominoperineal excision of the rectum (Miles) employing Cope clamp. The longed segment of the proximal end of divided bowel is pushed lengthwise through a small stab wound in the left iliac region to establish a single-barreled colostomy; the distal end of the bowel with its attached segment is pushed down below the pelvic peritoneum and a new pelvic floor is established (C. Sert).

moid thus diminishing the opportunity for contamination.

The patient is then turned on his side or on the abdomen with the hips elevated. The anus is closed with a purse-string suture, lateral incisions are made and dissection about the rectum is carried out all just as in a posterior resection. There is very little bleeding because of ligation of the inferior mesenteric artery. The rectum together with the retroperitonealized sigmoid is extirpated with rapidity and ease.

Radin Operation (1)—The two stage

one stage maneuver.

Colostomy and exploration are carried out at the first stage and consist in dividing the bowel establishing a single-barreled colostomy as in the Miles operation and dropping the inverted rectal end back into the peritoneal cavity, closing the abdomen and then waiting a period of at least three weeks before radical removal of the isolated segment which is accomplished by a combined abdominoperineal operation. Rectal irriga-

* Baile and Graham: Cancer of the Colon and Rectum. Charles C. Thomas Publisher.

tions are carried out between stages. In the second stage the patient is placed on the operating table as for posterior resection of the rectum and the rectum is mobilized up to the peritoneum also as in the latter procedure and encased in a rubber glove which is tied tightly about the cuff. This is pushed up into the hollow of the sacrum and the wound is then closed.

Next the patient is placed on his back and the anterior portion of the dissection is carried out. The peritoneum is incised on both sides of the previously divided sigmoid; the inferior mesenteric vessels are ligated

procedure which retains the principles of the radical abdominoperineal operation is considerably less formidable than either the Miles operation or the preceding one of which it is a modification. At the first stage abdominal exploration is carried out through a right split muscle incision and a cecostomy is established (Fig. 579). The second stage consists of a perineoabdominal operation. First the rectum is mobilized and enclosed in a rubber glove; the patient is then turned over and the abdomen is opened. A single-barreled colostomy is then established as previously described except that

Fig. 580.—Penneal excision of the rectum. The anterior portion of the dissection has been carried down to the membranous urethra and the prostate gland and seminal vesicles are shown dissected clear. Peritoneum is opened to permit further mobilization of the sigmoid after division of the superior mesenteric vessels (insert a). Insert b shows the end of sigmoid inverted and the peritoneum being sutured at a higher level on the sigmoid. (Adapted from Rankin and Graham*)

close to their origin the recto sigmoid is freed by blunt dissection in the hollow of the sacrum; the rubber glove is grasped and the entire segment of sigmoid, rectum and anus is lifted out of the abdomen. The gauze pack is inserted into the large cavity thus opened to be removed later through the posterior wound. A new pelvic floor is established by approximation of the lateral peritoneal flaps and the abdominal wound is closed without drainage.

Rankin Operation (2).—This alternative

* Rankin and Graham: Cancer of the Colon and Rectum. Charles C. Thomas Publisher.

it is unnecessary to invert the rectal end. The remainder of the procedure is identical with the preceding one. The freed sigmoid and rectum are lifted out of the hollow of the sacrum and a new pelvic floor is made; the abdomen is then closed without drainage. This operation permits fully as radical a resection as the Miles operation in one stage yet it has a mortality no greater than that of posterior resection.

Colostomy and Posterior Resection (Perineal Incision).—A double-barreled colostomy is first established and two or three weeks later the resection is carried out. The

writers prefer the left inguinal colostomy, a description of which is given in detail in the section on carcinoma of the colon (Fig 579). For the posterior resection the patient lies prone with the hips elevated. A purse-string suture is placed about the anus, two elliptical incisions are made to extend from a little above the sacrococcygeal joint around to the center of the perineum. The coccyx may or may not be removed as seems best in each case.

The rectum is freed (1) of its attachments posteriorly by blunt dissection in the hollow of the sacrum (2) of its lateral attachments by extending the original incisions down through the levator ani muscles and lateral ligaments which contain the medial hemorrhoid vessels and (3) of its anterior attachments by traction on the distal end of the bowel as sharp dissection is carried upward to the reflection of the peritoneum in the female and to the capsule of the prostate and seminal vesicles in the male (Fig 580). The peritoneal cavity is entered, sufficient sigmoid is pulled down to enable resuture of the peritoneum 5 to 7 cm above the original point of attachment and the bowel is divided between clamps with a cautery some distance above the growth. The end of the bowel is then inverted and a large rubber dam or oiled silk packed with gauze is placed in the cavity which remains. This provides adequate drainage of serum and temporarily supports the frail perineal floor. In those instances in which the sulfonamides appear to be indicated, dependence is placed on sulfadiazine administered parenterally rather than on local application of these drugs.

Mortality and Recurrence.—The mortality following radical and palliative operations on the large bowel contrary to an apparently widespread opinion is not prohibitive nor are fatalities from recurrences so discouragingly numerous as was the case a quarter of a century ago. At about that time barely 25 per cent of the diagnosed cases were operable, 20 to 50 per cent of the patients who were operated on died in the hospital and well over 85 per cent of the survivors eventually succumbed to recurrence. In striking contrast to these results surgeons during the past decade have reported

operability rates as high as 65 per cent for large series of cases while a comparative study of the mortality rate for individual surgeons and institutions by five year and ten year periods has revealed a progressive decline until now the general rate for all types of operations in the hands of experienced surgeons approaches 10 per cent. Moreover the incidence of recurrence as determined for numerous large groups of cases varies from 25 to 50 per cent which is an improvement of from 40 to 60 per cent over the best available figures several decades ago. In other words until relatively recent years fewer than 5 of 100 patients with carcinoma of the large bowel were alive five years after operation whereas now it can reasonably be expected that between 30 and 50 will be living at the end of such a period. As a matter of fact a study of any statistical data indicates that more patients with carcinoma of the large bowel and rectum are found to survive over a given period of years than those with carcinoma of any other portion of the gastrointestinal tract.

XXX. THE LIVER AND BILIARY SYSTEM

THE LIVER

INJURIES OF THE LIVER

Injuries of the liver may be divided into (1) penetrating and (2) subcutaneous types the former occurring more frequently than the latter. In a series of reports of 752 cases of injury to the liver collected by Thole 492 were penetrating (292 stab and 200 gunshot) wounds and 260 were subcutaneous injuries. The liver is the most frequently injured abdominal viscus. Of Kruc's 60 cases 83 per cent were due to penetrating wounds (68 per cent gunshot and 15 per cent stab) and 17 per cent were subcutaneous. According to Andersson lesions of the liver and gall bladder occur in 10 per cent of the open and 19.5 per cent of the subcutaneous abdominal injuries. The mechanism of rupture may vary according to the type of injury. Briefly the types are (1) direct trauma to the liver caused by a kick, blow or fall on the abdomen, (2) compression of the liver between a force applied to the abdominal wall and the vertebral column as when a wagon wheel passes over the abdomen, (3) contrecoup injury resulting from a fall on the head or feet, and (4) bursting injury as a result of a jack-knifing of the body as occasionally occurs in an infant during delivery (Ringers). Traumatic rupture occurs more frequently in a diseased liver especially one in which there is chronic passive congestion as a result of cardiac failure or one in which there is malignant change. Spontaneous rupture may occur.

Pathology.—Subcutaneous injuries to the liver are divided into three types: (1) true ruptures, those in which there is rupture of the capsule and parenchyma of the liver; (2) subcapsular injuries, those in which there is injury of the parenchyma without injury to the overlying capsule; and (3) central ruptures, those in which a localized contusion occurs within the substance of the liver without involvement of the surrounding portion. Subcutaneous injuries espe-

cially true ruptures involve the right lobe most frequently and usually the upper convex surface. True ruptures occur most frequently in the sagittal plane and vary from a small fissure extending only through the capsule to complete division of the liver. Profuse bleeding into the peritoneal cavity is usual. Subcapsular rupture which also occurs most frequently in the right lobe is characterized by the tearing of Glisson's capsule from the parenchyma and by the collection of blood between the hepatic substance and the capsule (Vance). Central rupture of the liver occurs as a result of movement of the various cellular layers in the liver caused by bending or torsion of the viscus (Andersson). Because of their similarity to cerebral apoplexy in which hemorrhage is surrounded by normal brain tissue these injuries have been designated as apoplexy of the liver (Andersson). A central rupture may increase progressively in size owing to increased pressure and subsequent necrosis of the parenchyma followed in turn by hemorrhage. Infection of a subcapsular and especially of a central rupture of the liver is likely to occur because of the almost constant presence of micro-organisms in the parenchyma of the liver. Hemorrhage in a true rupture is more likely to continue and to be severe than in the subcapsular or the central type. In spite of the low vascular pressure in the portal system hemorrhage from the liver tends to continue because the portal radicals in the liver have thin walls contain few elastic fibers and have no valves (Alessandri). Bleeding is prolonged and coagulation delayed because of the mixing action of the respiratory movements and the admixture of bile with the blood. In all types of trauma to the liver there is injury of the parenchyma and tearing of the bile ducts. In a penetrating or subcutaneous true rupture of the liver bile escapes into the peritoneal cavity varying in quantity from a relatively small amount to several liters.

Symptomatology.—The principal symptoms in injury of the liver are dependent on

hemorrhage from the liver which is most evident in a penetrating wound. The first manifestation of injury is shock from which the patient may recover temporarily unless there is massive hemorrhage. Irrationality, vomiting and irritability were present in 21.18 and 11 per cent respectively of Krieg's cases. Profound anemia develops. The pulse rate may or may not be increased. As a result of the escape of blood and bile into the peritoneal cavity in a case of penetrating or subcutaneous rupture there is an increase in the amount of peritoneal fluid as evidenced by dullness in the flanks. A fullness is palpable in the cul-de-sac of Douglas on rectal or vaginal examination. Bradycardia due to absorption of bile salts when present is of diagnostic importance and is contrasted with the tachycardia usually accompanying severe loss of blood (Finslerer). Bradycardia is found relatively infrequently and its absence is of no clinical significance. Pain in the upper right abdominal quadrant which is likely to be referred to the right shoulder is frequent. Tenderness and muscular rigidity especially marked along the right costal margin are prominent signs. The temperature at first is subnormal but later is elevated. Examination of the blood shows progressive anemia and increasing leukocytosis indicative of hemorrhage. As a result of absorption of bile salts from the peritoneum or from the liver itself there may be jaundice and in cases in which there is little hemorrhage edema may develop.

Prognosis.—The prognosis in injury of the liver depends on the type and the extent of the injury, whether it is penetrating or subcutaneous, the condition of the patient and the time of treatment. The mortality rate in penetrating injuries is lower than in subcutaneous injuries, probably because the former are likely to be recognized earlier. Boljarski reported a 33.3 and a 30.5 per cent mortality rate respectively in stab and gunshot penetrating injuries and an 85.3 per cent mortality rate in subcutaneous injuries. Thole found that in both subcutaneous and penetrating injuries the mortality rate in the first six hours was 39 per cent whereas after twenty-four hours it was 75.4 per cent in the penetrating injuries and 80.3 per cent in the subcutaneous injuries. Boljarski's figures indicate the

value of early operation. His mortality rate for patients operated on within two or three hours after injury was 15 per cent whereas after twenty-four hours it was over 50 per cent. Death occurring within the first seventy-two hours is usually the result of hemorrhage and shock, whereas after the fourth day it is caused by biliary or septic peritonitis. Irrationality, irritability and vomiting are particularly ominous signs. In Krieg's series in which all three manifestations occurred or in which one of the manifestations persisted two days or longer none recovered. Of those showing both irrationality and irritability only 15 per cent recovered.

Complications.—The complications of injury of the liver are: (1) massive hemorrhage (hemorrhage and shock were the cause of death in 73 per cent of Krieg's fatal cases); (2) peritonitis either as a result of irritation of the peritoneum by the bile salts (chemical peritonitis) or as a result of the escape of microorganisms into the peritoneum from the bile (biliary and septic peritonitis were the cause of death in 19 and 27 per cent respectively); (3) emboli consisting of pieces of liver; (4) sequestration of the hepatic substance; (5) thrombosis of the portal vein; (6) hepatic suppuration (11 per cent of the pyogenic hepatic abscesses in our series were due to trauma); and (7) rare, acute yellow atrophy (Peter).

Diagnosis.—The diagnosis of penetrating injury of the liver is not difficult because the wound directs the physician's attention toward the liver. The diagnosis is more difficult in a case of subcutaneous injury but if in all cases of direct compression trauma of the abdomen as well as in all cases of a fall on the head or feet especially when associated with intra-abdominal hemorrhage, the possibility of injury to the liver is considered the diagnosis is not difficult. Progressive hemorrhage as evidenced by the appearance of the patient and the increasing amount of peritoneal fluid especially when associated with bradycardia is suggestive of rupture of the liver. Increasing leukocytosis determined by repeated examination of the blood is indicative of massive hemorrhage and is confirmatory of rupture of an intra-abdominal viscus. Exploratory aspiration of the peritoneal cavity will reveal evidence

portation to the liver. These lesions are frequently of such a character that they are not recognized clinically, the hepatic abscess apparently not being preceded by an antecedent lesion; i. e. cryptogenic. In our series these cases represented the largest group, 28 of 47 cases (59.5 per cent).

Pathology.—In contradistinction to amebic abscess, pyogenic abscess of the liver is usually multiple. Many microorganisms gain entrance to the portal system and are carried to the liver in large quantities. The abscess is more frequently found in the right

sweats. Pain in the upper portion of the abdomen, especially on the right side and referred to the right shoulder, is a prominent complaint. In our series fever, pain and tenderness were most frequently encountered, being found in approximately 90 per cent of cases. On physical examination enlargement of the liver and extreme tenderness along the costal margin are noted. The patient appears very ill if the process has persisted long; he is cachectic. Nausea and vomiting, loss of weight and jaundice were observed in one third of our cases. There is

Fig. 570.—Retroperitoneal operation. Drawing showing a transverse incision through the bed of the twelfth rib at the level of the spinous process of the first lumbar vertebra, passing through the attachment of the diaphragm below the reflection of the pleura.*

lobe of the liver, probably because, as shown by Serje, Copher and Dick, blood from the right half of the colon is carried to the right lobe of the liver. Pathologically, the abscesses vary from those of microscopic size to large coalescing cavities surrounded by a pyogenic membrane. Microscopically, there are the characteristic changes of acute and chronic inflammation. Contained within the abscess cavity is typical pus. Occasionally a pyogenic abscess may be solitary.

Symptomatology.—The principal symptoms are fever of a remittent or intermittent type associated with chills and profuse

a marked increase in the number of leukocytes (20,000) with a corresponding increase in the number of polymorphonuclear leukocytes.

Diagnosis.—The occurrence of chills and fever, especially when associated with profuse sweats in a patient with suppurative appendicitis or some other suppurative lesion in an area drained by the portal system is indicative of pyelophlebitis and a hepatic abscess until proved otherwise. In contradistinction to amebic abscess of the liver, the

* Ochsner and Crain: Ann. Surg. 29: 3 B. L. p. 1111, 1920.

leukocyte count is higher and the relative increase in polymorphonuclear leukocytes is greater. Roentgenograms are of value because of the elevation of the diaphragm and the increase in the size of the liver. In contrast to cases of amebic abscess exploratory puncture is never justified because of the danger of contaminating an uninvolved serous cavity.

Prognosis—The prognosis in cases of multiple pyogenic hepatic abscess is extremely grave, the mortality rate being approximately 70 per cent. This high rate is due

in the cases in which operation was performed. Furthermore, the type of operative procedure is of prognostic importance as shown by the 33 per cent mortality rate in the cases in which drainage was extraperitoneal in contrast to the 71 per cent mortality in those in which it was transpleural or transperitoneal.

Complications—The complications consist principally of rupture of the abscess into the peritoneal and pleural cavities and extension into the systemic blood stream with the development of septicemia. In our

Fig. 501—Drawing showing method of approaching an abscess in the subpleural space and liver retroperitoneally. The peritoneum is peeled from the undersurface of the diaphragm until the abscess cavity is reached.*

probably not only to the multiple lesions in the liver which are difficult to recognize and to drain but also to thrombophlebitis of the portal vein which is responsible for continued involvement of the liver. In the case of a solitary pyogenic abscess of the liver the prognosis is not so grave. Ochsner, Gage and Garside were able to collect from the literature reports of 15 cases in which recovery followed operation. The prognosis is dependent to a great extent on the type of therapy instituted. In our series the mortality rate was 100 per cent in the cases in which operation was not performed and 65 per cent

Under no circumstances should a pyogenic hepatic abscess be drained transpercutaneously because of the danger of contaminating the pleural cavity and thereby greatly increasing the mortality rate (see under the discussion on prognosis). This and contamination of the peritoneal cavity can be obviated by the retroperitoneal operation (Figs 590 and 591). In those cases in which there is associated pyelephlebitis ligation of the portal vein or its radicals as suggested by Wilms should be done in order to prevent continued discharge of infected emboli into the liver. In cases of multiple abscesses incision and drainage by the retroperitoneal or extraperitoneal technique should always be carried out but is usually of little avail.

AMEBIC ABSCESS OF THE LIVER

Amebic abscess of the liver occurs more frequently than is commonly supposed. Amebiasis which previously was considered a disease of the tropics is ubiquitous and the possibility of hepatic involvement should always be seriously considered. The causative agent of amebic abscess is the *Entamoeba histolytica* and a contributing factor is alcoholism. The incidence of amebic abscess varies considerably. The ratio of the number of patients with amebic abscess to the number with amebic dysentery admitted to the Charity Hospital in New Orleans is 1 to 7.5. Amebic abscesses according to the collected reports occur most frequently in young adults. In our series of

cases 50.3 per cent occurred in patients between the ages of thirty and fifty years. Males are more frequently affected than females. A study of our series disclosed that the ratio of males to females was 8 to 1 but in most reported series the predisposition in males is even greater.

Pathogenesis.—The amebas are carried through the portal vein from specific amebic ulcers which may be located in any portion of the large bowel to the liver where specific hepatitis is produced whereas in the majority of cases of amebic dysentery the lesion is principally in the left half of the colon. If the lesion is on the right hepatitis may also occur. In fact hepatitis is more likely to follow right-sided infection as the result of lack of recognition and failure of institution of treatment because of the absence of dysenteric manifestations. Amebic abscess occurs most frequently in the right lobe of the liver probably because as shown by Séregé and by Coppler and Dick blood from the right half of the colon passes largely to the right lobe. In a series of 2121 cases collected from reports in the literature the right lobe was found to be involved in 1792 (84.4 per cent) and the left lobe in 329 (15.5 per cent). In the authors' series of 90 cases the abscess was in the right lobe in 95 cases (95.5 per cent) and in the left lobe in 4 cases (4.5 per cent). The higher incidence of involvement of the right lobe in the authors' series as compared with that in the collected cases is explained by the fact that a large number of cases studied at autopsy are included in the latter. Multiple abscesses are usually associated with large extensive intestinal ulceration but a single abscess usually follows less extensive infection. An amebic abscess is usually solitary and is found most frequently in the periphery usually in the diaphragmatic portion of the liver. The amebas produce hepatitis which may subside spontaneously or under treatment or may progress to liquefaction. The latter is largely due to the proteolytic activity of a soluble toxin produced by the amebas (Crug). Rogers has shown that amebic abscess results from extension of the process along the vein from the central cavity and that the original lesion is due to anemic necrosis produced by plugging of the portal radical by the amebas and the lytic

action on hepatic tissue of toxic products elaborated by the amebas. Amebic abscess is characterized by absence of leukocytic infiltration. Characteristically the large abscesses surrounded by fibrous tissue contain the chocolate brown pus, the finding of which establishes the diagnosis. In this pus are found few or no leukocytes, the material being composed of cellular detritus and blood. The abscesses vary in size from a microscopic to a large solitary abscess filling an entire lobe of the liver. Amebic abscesses are sterile in the majority of instances, 84.7 per cent in the collected series and 81.5 per cent in our series. Active amebas are found only in small abscesses but can almost in-

stant. Tenderness along the right costal margin and enlargement of the liver occur in approximately 80 per cent of cases. In cases of amebic abscess as emphasized by Rogers and Manson-Bahr there is moderate leukocytosis as contrasted with the marked leukocytosis which is seen in cases of pyogenic hepatic abscess. Characteristically there is not the disproportionate increase in the polymorphonuclear leukocytes that is found in cases of the pyogenic type of abscess. The leukocyte count averages about 15,000 and the polymorphonuclear leukocytes about 80 per cent. A high leukocyte count is indicative of multiple abscesses and offers a bad prognosis (Rogers).

Fig 592—*a* Anteroposterior roentgenogram of the abscess which has ruptured into the subphrenic space *ward into the lower pulmonary field and obliteration of the cost and diaphragm in the same case showing* elevation of the anteroposterior angle

elest and diaphragm of a patient with an hepatic with elevation of the diaphragm localized bulging up of the cardiophrenic angle *b* Lateral roentgenogram characteristic elevation of the diaphragm and obliteration of the anteroposterior angle

variably be identified in scrapings from the wall of the abscess.

Symptoms and Signs.—The systemic manifestations of amebic abscess consist of fever, profuse sweating, weakness, anorexia, loss of weight, nausea, vomiting, malaise and chills. Jaundice occurs infrequently. The fever may be of the intermittent or remittent type. A history of diarrhea in a series of 741 collected cases including our cases was present in only 58.2 per cent whereas diarrhea at the time of admission was present in only 21.5 per cent of our cases. Of the local manifestations, pain in the upper right abdominal quadrant, which may be referred to the right shoulder, is the most con-

Diagnosis.—Of diagnostic importance are elevation and immobilization of the diaphragm as determined roentgenologically. Granger has emphasized that in a case of uncomplicated hepatic abscess a distinct bulging of the diaphragm with a pointing upward into the lower pulmonary field is noted. In those cases in which the abscess has ruptured into the subphrenic space there is obliteration of the cardiophrenic angle in the anteroposterior roentgenogram and there is obliteration of the anteroposterior angle in the lateral view (Fig 592 *a*). Amebic hepatitis or an abscess of the liver should be considered when there is persistent enlargement of the liver as oc-

ated with pyrexia and moderate leukocytosis. A history of previous dysentery is confirmatory evidence. The diagnosis can be corroborated by the finding of typical choco-bile-brown pus in the material aspirated from the abscess. Aspiration should be done in such a way that the aspirating needle does not traverse a free serous cavity and an immediate smear of the pus should be made in order to eliminate pyogenic infection.

Prognosis—The prognosis in cases of amebic abscess of the liver depends on (1) the multiplicity of lesions in the liver (2) the general resistance of the patient (3) secondary infection of the abscess cavity and (4) the type of treatment employed. Rogers was able to decrease the mortality rate from 68 per cent after open drainage to 14 per cent with closed drainage. Chatterji reports a mortality of 16 per cent after closed drainage. In a series of 4334 case reports collected from the literature and including our own cases in which open operation was performed the mortality rate was 43.8 per cent whereas in a series of 509 cases in which conservative treatment was used the mortality rate was 6.4 per cent. In our series of 198 cases the mortality rate following open drainage was 21.6 per cent in contrast to that of 3.6 per cent following aspiration and the use of amebicides.

Complications—Complications of amebic abscess of the liver are the result of rupture or direct extension into one of the adjacent viscera, secondary inflammation and suppuration, thrombosis and embolism. Pleural and pulmonary involvement are the most frequent complications. Rupture into the pleural cavity and lungs occurs not infrequently. The percentage of cases in which this occurs varies from 3 to 40.8 per cent. This complication occurred in 15.8 per cent of our cases. When rupture into the lung occurs, evacuation of the abscess through the bronchus offers a relatively good prognosis. Other complications include rupture into the peritoneal cavity, into the pericardium, into the abdominal wall with involvement of the abdominal parietes and into the colon. Cerebral abscess and ruptures into the portal vein, inferior vena cava and hepatic veins have been reported but are rare complications.

Treatment—The reduction of the mortality rate in cases of amebic abscess of the liver has been due to two factors: (1) the administration of the specific drug emetine both preoperatively and postoperatively and (2) the appreciation that amebic abscess of the liver is sterile and that every precaution should be made to prevent its contamination with pyogenic microorganisms. Since it is frequently difficult to differentiate amebic hepatitis from abscess, emetine should always be used first unless there is an urgent indication for operation. Prior to Rogers' work amebic as well as pyogenic abscesses of the liver were treated by open drainage. After drainage the patient with amebic abscess did well for from one to three days, then toxemia developed and he became progressively worse and finally died. Rogers showed that this was due to secondary infection of a previously sterile amebic cavity. The combined mortality rate for patients treated by open drainage in a collected series was 43.8 per cent as contrasted with that of 6.4 per cent for those treated by closed drainage and emetine. If at the preliminary aspiration there is evidence of secondary infection and if microorganisms are present in the pus, open drainage is essential. Closed drainage consists of repeated aspiration of the abscess cavity by means of a large trocar and evacuation of the contents of the abscess. This is followed by injections of emetine. Emetine should be given in grain (0.064 Gm.) doses daily, not exceeding a total dose of 10 grains (0.648 Gm.) because of the danger of producing myocardial degeneration.

ECHINOCOCCUS CYSTS OF THE LIVER (HYDATID CYSTS)

Etiology—Echinococcus cysts of the liver are caused by the development of the larval or bladder stage of the tapeworm *Taenia echinococcus* the adult stage of which is found in the intestine of dogs and other canines.

Echinococcus cyst of the liver is rare in the United States but is common in regions of pasturage (Iceland, Australia, Argentina and elsewhere). In some localities there is a greater frequency in the male whereas in other regions the opposite is found. It is usually a disease of adults.

Pathology—The cyst is usually located in the right lobe sometimes attaining such size as to occupy the entire lobe. Not infrequently there are multiple cysts. The cyst wall is pearly opalescent, elastic and laminated and has a granular inner lining. While the parasite is alive the content is a clear fluid but after the echinococcus dies the fluid becomes turbid and contains albumin. A fibrous capsule is formed around the cyst as a result of pressure and atrophy of the surrounding hepatic parenchyma. In this capsule are found numerous biliary canaliculi and vessels with some mononuclear and eosinophilic infiltration. Small daughter and granddaughter cysts also may be present in the chitinous membrane. Occasionally a hydatid cyst undergoes spontaneous death. Because of atrophy of the liver around the cyst there is usually observed resultant compensating hypertrophy of other parts of the liver.

Symptomatology—Clinical manifestation of the disease may never be present. Frequently there is a dragging sensation in the hepatic region and pain may be referred to the shoulder. Occasionally urticaria, dyspepsia, nausea and vomiting, constipation, jaundice and pseudo biliary colic may be

present. Local manifestations are more prominent than the constitutional ones. Depending on the location of the cyst the liver is enlarged upward or downward. A cyst near the dome of the liver may cause upward displacement of the diaphragm with signs of pleural effusion. When the cyst is anteriorly situated there is characteristic protrusion in the hypochondriac region. If it is inferiorly located a tense elastic tumor may be palpated. The characteristic hydatid thrill is inconstant but when present it is strongly suggestive.

Diagnosis—The condition should be suspected when there is cystic enlargement of the liver over a long period with few or no constitutional manifestations particularly in a patient who lives in a district devoted to pasturage. The hydatid thrill is confirmatory but not pathognomonic. The flood picture characteristically reveals a marked increase in eosinophils. Roentgen examination may be helpful. The complement fixation test is still technically difficult and although a positive result in competent hand is significant a negative result should not exclude the condition. The intradermal test of Cason is important and helpful. Exploratory puncture should be performed with extreme caution and hesitancy.

Complications—Rupture of the cyst and suppuration are the gravest dangers. Perforation may occur into the stomach, intestines or thoracic cavity. Rupture into the peritoneal cavity frequently results in severe or even fatal shock.

Prognosis—Spontaneous cure is occasional in young persons the prognosis is better. The total mortality has been estimated at 15 per cent (Deve). The outlook with operation is generally favorable.

Treatment—The treatment is strictly surgical. Some surgeons prefer the two stage whereas others use the one stage operation unless it is absolutely contraindicated. After the abdomen has been opened and the peritoneal cavity has been carefully protected with gauze packs the cyst is aspirated and 2 per cent formalin is injected. The cyst is then incised and the chitinous membrane removed. After the cavity has been wiped out with formalin immediate closure is advocated if no contraindications are present.

ACTINOMYCOSIS OF THE LIVER

Actinomycosis of the liver is extremely rare and is usually secondary. The primary focus is commonly in the alimentary canal, the infection spreading by direct extension or via the blood stream. The liver is usually enlarged and presents a characteristic honeycombed appearance owing to the coalescence of numerous small abscesses containing the typical bright yellow granular pus. Surface abscesses usually form but perforation may occur. The clinical manifestations are not characteristic. Pain and swelling in the right hypochondriac region, fever, chills, gastrointestinal disturbances, anemia and leukocytosis may be present. The prognosis is always grave and results of treatment are not encouraging. Incision and drainage of the abscess should be adequately performed. Iodides in large doses (up to 1000 grains daily) should be given as well as deep roentgen therapy.

SYPHILIS OF THE LIVER

Syphilis of the liver is rarely of concern to the surgeon except in the tertiary stage and as a consideration in a differential diagnosis. In the tertiary stage of gumma formation the clinical manifestations may simulate portal cirrhosis, malignant neoplasm, hydatid cysts, abscess, cholelithiasis and actinomycosis. Differentiation is based on a positive Wassermann reaction, a history of syphilis, syphilitic manifestations elsewhere and obscure enlargement of the liver. In all doubtful cases a thorough course of mercurials and iodides should be tried.

TUBERCULOSIS OF THE LIVER

Tuberculosis of the liver is of little importance clinically and of less importance surgically as it is usually only one manifestation of generalized tuberculosis.

BENIGN TUMORS OF THE LIVER

Benign tumors of the liver are of more interest to the pathologist than to the surgeon. Lipoma, fibroma and myoma have been reported but are extremely rare. adenoma occurs infrequently. Cavernoma or cavernous hemangioma is the most frequent tumor of the liver. It generally occurs on the surface of the liver, usually as a small bluish red tumor immediately beneath the capsule. Its presence is rarely recognized except at autopsy or during operation. Occasionally the tumor becomes very large and produces hepatic enlargement usually as the only clinical manifestation.

PRIMARY CARCINOMA OF THE LIVER

Because of its rarity and its surgical unimportance, primary carcinoma of the liver warrants only a brief discussion. The incidence varies from 0.17 to 0.3 per cent of all necropsies and from 1.5 to 3 per cent of all cancers (Abel). It is most frequent in the fifth and sixth decades although there have been cases recorded in infants and children (Kilfox and Terry). There is a greater frequency of occurrence in males.

Morbid Anatomy.—Carcinoma may originate in the parenchymatous hepatic cells or the intrahepatic biliary duct cells. The former tumor is termed a hepatoma, the latter a cholangioma, a combination of the two is called a mixed tumor. Clinically there are three types of primary carcinoma of the liver: 1. *Nodular or multiple primary carcinoma*, the common form, is a highly malignant rapidly growing type characterized by multiple grayish bile-stained or hemorrhagic and necrotic nodules usually involving the entire organ. Histologically there is great variation in structure with a tendency toward reproduction of the more malignant features of carcinoma. 2. *Primary massive carcinoma* is characterized by a large single white or yellowish rather friable mass often occupying almost an entire lobe and not infrequently surrounded by small secondary growths. Considerable variation in structure may be observed microscopically with constantly present areas having a definite resemblance to normal hepatic cells. 3. The *diffuse form* is characterized by numerous small nodules and frequently infiltrates the

entire liver which is often small and contracted but sometimes slightly enlarged. The nodules are surrounded by connective tissue and grossly the picture so closely resembles that of hypertrophic cirrhosis that the malignant growth can be recognized only by microscopic examination. This latter characteristic has given rise to considerable discussion apropos of the possible etiologic relation of cirrhosis to cancer.

Symptomatology—As is characteristic of malignant disease elsewhere there is usually progressive loss of weight and strength with increasing secondary anemia. The onset is frequently insidious with gradually developing discomfort in the right hypochondrium, anorexia, emaciation, hepatic tumor, jaundice and ascites. Fever is frequently present especially when the tumor is of the rapidly growing type. The spleen is seldom enlarged. The disease usually runs a rapid course terminating within three to four months.

Diagnosis—Rapid and progressive enlargement of the liver, pain, loss of weight and strength, secondary anemia, jaundice and ascites are indicative of carcinoma of the liver. Roentgenographically the liver is fixed and enlarged disproportionately upward (Strong and Pitts). Primary disease elsewhere must always be suspected and differentiated as well as cirrhosis, syphilis, echinococcus cyst, abscess and gallstone in the common bile duct.

Treatment—Palliative therapy directed toward the alleviation of pain and discomfort is practically all that can be given. Resection of the growth is ideal if possible and if it can be definitely determined at operation that it is primary in the liver. Roentgen and radium treatment are of no practical benefit.

PRIMARY SARCOMA OF THE LIVER

Primary sarcoma of the liver is very rare. Rolleston recognizes five types: (1) primary massive sarcoma characterized by a large tumor mass usually in the right lobe with frequent hemorrhage and cystic degeneration; (2) nodular or multiple primary sarcoma characterized by numerous nodules scattered throughout the hepatic substance; (3) diffuse or infiltrating primary sarcoma occurring most frequently in infants; (4)

primary sarcoma arising in a cirrhotic liver which is extremely rare; and (5) primary melanotic sarcoma the occurrence of which is questionable.

The clinical manifestations are excessive weakness which appears to be out of proportion to the general physical condition, hepatic pain, early anemia, definite enlargement of the liver, rapid emaciation and loss of weight. Jaundice and ascites are less common than in carcinoma. Death usually intervenes within three to four months. Treatment is palliative. Cases have been reported in which operative removal was followed by recovery, but these are exceptional.

SECONDARY CARCINOMA OF THE LIVER

Secondary carcinoma of the liver is frequent and occurs in about half of all patients with malignant disease. The primary growth is most frequently in the stomach, colon, esophagus, pancreas, gallbladder or uterus. There is a slightly greater frequency of occurrence in women and the average age is over forty. The liver is usually enlarged with a diffuse infiltration of metastatic nodules frequently near the surface. These nodules are rather hard except if enlarged when as a result of degeneration and necrotic changes they may become soft. This latter development is also the cause of the characteristic umbilication or central depression of the nodules. Secondary metastatic involvement may produce pain as a result of peritonitis or may cause ascites and jaundice as a result of pressure and engorgement.

SECONDARY SARCOMA OF THE LIVER

Secondary sarcoma of the liver is less frequent than secondary carcinoma and is usually due to metastasis from a melanotic sarcoma of the uveal tract, rectum, skin, adrenal body, medullary or bones. Only palliative therapy can be instituted in cases of metastatic tumors as they are invariably inoperable.

CHOLECYSTITIS, CHOLELITHIASIS, CHOLEDOCHOLITHIASIS AND AS- SOCIATED DISEASES OF THE LIVER

Improved conceptions with regard to the correlation of various functions of the body have led to a wider recognition of the disturbances that are directly attributable to or remotely associated with, disease of the biliary tract. A thorough knowledge of the anatomy, physiology and pathology of the biliary tract is the first requirement for skillful attention to the problems that arise from changes occurring in that system. Anything less than this will be inimical to the best interests of the patient.

Whether surgical treatment will be necessary will depend on the interpretation of the signs and symptoms. The principles and technique of operations for the correction of biliary disturbances have been established for a long time. Probably nowhere in the practice of surgery is judicious care so often associated with prompt recognition of anomalous anatomical relationships, for in the biliary system such anomalous conditions are of comparatively frequent occurrence. An oversight or a mistake in carrying out the technical steps of the procedure may result in loss of life from hemorrhage or may lead to protracted invalidism as a result of calculous obstruction or injury to the common bile duct or hepatic ducts.

Physiology.—The liver is one of the major body depots of glycogen storage and consequently plays an important part in regulation of the quantity of sugar in the blood. Adequate store of glycogen aids markedly in the resistance of the liver to injurious effects of many toxins. Disturbance of the concentration of sugar in the blood rarely is encountered in pathologic hepatic or biliary conditions and when it is encountered it appears chiefly as hypoglycemia in chronic hepatic disease.

The liver likewise plays an important part in the metabolism of proteins, including deamination of amino acids and formation of urea, destruction of urea, production and storage of body proteins, maintenance of serum proteins and formation of prothrombin necessary in coagulation of the blood. Furthermore, the liver is important in the metabolism and storage of fats. Detoxification is another important function of

the liver, but concerning its exact mechanism little is known. The liver is responsible for the elaboration of bile salts and excretes them in the bile.

The liver has remarkable regenerative power. Mann and Fishback removed as much as 70 per cent of the total weight yet in a few weeks the remaining hepatic tissue had grown nearly to the normal total amount. Biliary obstruction and cirrhosis act to depress this regenerative power, yet although hepatic functions are impaired selectively as shown by tests, metabolism of carbohydrates and protein remains normal for some time.

There are many known facts which indicate that the gallbladder is of physiologic significance yet by no means of as great importance as the liver. The gallbladder stores and concentrates bile, thus correlating the secretory activities of the liver with those of the

Fig. 393.—The gallbladder and extrahepatic biliary ducts showing a frequent anomaly of the blood vessels in which the right branch of the hepatic artery crosses in front of the common hepatic bile duct.

gastrointestinal tract. Loss of the gallbladder is compensated for by dilatation of the extrahepatic bile ducts. The relaxation of the sphincter and the emptying of the gallbladder have been shown to be closely associated with the ingestion of food. The gallbladder empties by contraction of its intrinsic musculature and this contraction and emptying are coincident with the production from the duodenal mucosa of a true hormone, cholecystokinin.

For measuring hepatic function many tests have been devised. The van den Bergh test is valuable for ascertaining the amount of serum bilirubin retained in the blood stream and also for distinguishing the obstructive and the hepatogenous jaundice, in which the reaction is direct from the hemolytic type of jaundice which gives an indirect reaction. The dye retention test of Rowntree and Rosenthal, the mustard test of Delprat, the hippuric acid test, the galactose tolerance test and the determination of the quantity of

serum phosphatase plasma cholesterol and cholesterol esters and of total serum protein are tests of hepatic function which may be of value in the differential diagnosis of complicating hepatic disease or jaundice and in determining surgical risks and preoperative and postoperative therapy. When there is a prolonged prothrombin clotting time failure to respond to vitamin K denotes impairment of liver function. Medical and surgical treatment of disease of the biliary tract will advance with and in proportion to further improvements in investigative diagnostic methods.

On the basis of the van den Bergh reaction McVee made a clinical classification of jaundice: 1 Obstructive jaundice caused by occlusion of the biliary tract by calculus a structure or neoplasm. The van den Bergh reaction is always direct. 2 Intrahepatic toxic or infectious jaundice dependent on actual damage to parenchymal liver tissue. The van den Bergh reaction is usually direct but may be indirect or diphasic. 3 Hemolytic jaundice to which the reaction is truly indirect since the bilirubin never has passed through the hepatic cells to be reabsorbed by the blood and lymph as in the first two types. The test is of value because direct surgical treatment of the biliary lesion can be of value only in cases of obstructive jaundice.

In recent years additional information in regard to the physiologic processes of the biliary tract has been gained through visualization of the common and hepatic ducts under the fluoroscope and by roentgenographic methods after injection of a nonirritating opaque substance into these ducts.

Pathology.—Mann and Bollman have emphasized the point that biochemical methods will not accurately indicate the amount of temporary or permanent hepatic injury caused by biliary stasis and infection. Because of the close parallel to the hydronephrosis seen in the kidney following ureteral obstruction the term hydrohepatosis has been applied to the condition found in the liver following protracted complete obstruction of the bile ducts. The ends of the ducts become clubbed and varicose. If infection is not present, the picture is that of hydrops of the entire biliary system. Microscopically the canaliculi are filled with biliary thrombi especially near the central hepatic veins the hepatic parenchyma is atrophic and the finer bile ducts at the periphery of the so-called "hepatic lobules are numerous and tortuous. Eventually there is leukocytic infiltration along the ducts and the hepatic cells at the bases of the acini atrophy. A slow replacement by fibrous tissue then takes place. The ducts are at first filled with bile but as time goes on this is replaced by the colorless mucus derived from the epithelial cells of the ducts. These cells also remove the bile pigment causing the change in color. Eventually if the process is allowed to go on the stage of advanced cirrhosis is reached and the liver is markedly decreased in size. If however the presence of micro-organisms complicates the picture there is suppurative cholangitis with multiple hepatic abscesses around the terminal biliary ducts. The entire system of ducts is filled with bile-stained pus the mucous membrane disappears leaving a shaggy submucosa and the walls and portal spaces are infiltrated with polymorphonuclear leukocytes. In the event the process becomes chronic, there is fibrosis of the walls

of the ducts and later the entire portal spaces and lymphocyes infiltrate the submucosa, particularly around the portal sacculi. Therefore, it must be remembered that with long-standing obstructive jaundice there is diffuse organic injury which is the result of the lack of normal hepatic function. In these cases surgical procedures aim at establishing proper biliary drainage to enhance anatomic and physiologic regeneration in the liver as much as possible, a complete return to normal however cannot be expected. Some investigators state that 10 per cent of the normal amount of healthy hepatic tissue may be adequate to carry on a normal function.

The changes in the liver and bile ducts which are so frequently observed in association with disease of the gallbladder can scarcely be interpreted as merely incidental. The peculiar appearance of the surface of the liver immediately adjoining an infected gallbladder or in conjunction with disease of the common bile duct is well known. This condition is often loosely termed hepatitis. However there is no uniformity of opinion as to the exact nature of the part which the condition may play in the manifestations of disease elsewhere in the biliary tract. Although on the basis of the clinical history and the improved tests of hepatic function, it is possible to make a fairly accurate estimate of the degree of hepatic injury and the consequent disturbance of function there is still a great deal to be learned concerning the cause and true extent of the changes that have taken place in the underlying hepatic tissue in the condition known as hepatitis.

It is probable that chronic cholangitis forms the basis of most microscopically recognizable lesions of the liver associated with infection in the gallbladder with or without obstructive lesions of the common bile duct. However the condition appears in a large number of different forms and under a variety of circumstances. Cholangitis is an inflammatory process occurring in and around the walls of the intrahepatic and extrahepatic bile ducts varying from a simple scar of the Haag epithelium to marked lymphocytic and polymorphonuclear leukocytic infiltration of the connective tissue of the entire portal spaces. Associated with this condition is proliferation of fibrous tissue that leads to tremendous thickening of the walls of the ducts. The description must be modified by the statement that although in most cases the changes are confined to the bile ducts proper such changes may extend to the intercellular biliary canaliculi and may there produce the condition known as biliary cirrhosis.

Although the usual conception of cholangitis is that it is the result of obstruction of the common bile duct with ascending lymphatic infection of the walls of the duct and portal spaces or that it is the result of ascending infection of the stagnant bile it should be recognized that cholangitis may occur as a hematogenous infection through the portal vein or hepatic artery or by direct extension from a diseased gallbladder through lymphatic structures to the liver. In the genesis of these conditions the element of infection is more significant than the presence of obstruction and although obstruction and retention of bile undoubtedly hasten and intensify the process once infection is established they do not by themselves produce cholangitis except after long periods. Cholangitis or

titis may be arbitrarily divided according to the degree of severity of the infection into the following classification: catarrhal, suppurative or gangrenous. However, a clear cut distinction such as is indicated by the classification is frequently impossible because of the fact that these pathologic stages are blended. The severity of an attack may be entirely without relationship to the pathologic picture presented by the gallbladder when it is examined grossly or microscopically. In the mildest forms there may be no visible change in the gallbladder beyond a little swelling of the mucosa that on microscopic examination reveals a lymphocytic and leukocytic infiltration of varying degrees. Later this extends throughout the walls which become edematous, soft and congested. The serosa exhibits a network of engorged vessels rapidly loses its smooth sheen, becomes dull and granular and readily adheres to surrounding structures. The mucous membrane is congested, is covered with sticky mucus and may exhibit here and there little ulcerations of the surface. Outpouring of a serous, fibrinous or bloody exudate alters the normal golden brown bile and renders the gallbladder tense and distended. If the process progresses further the contents are replaced by frank pus. Suppurative cholecystitis has occasionally been referred to as acute empyema, but the term empyema is more commonly used to describe the slow accumulations of pus in an old chronically infected gallbladder, a change associated with few symptoms. Finally, the mucous membrane becomes sloughy and necrotic and in places is shed entirely, leaving granulating areas or dark red, greenish or blackened patches of gangrene penetrating to the serosal surface. Areas of impending perforation are more commonly found near the fundus and are associated with the pressure of stones or other factors interfering with the nutrition of the walls. In the most severe cases, particularly if the cystic artery is occluded, gangrene of the entire wall ensues and perforation almost certainly follows. The natural course of acute cholecystitis is subsidence without perforation, leaving the gallbladder adherent to adjacent viscera or to the omentum but with chronic infection permanently established in the walls. Occasionally impaction of a stone

in the cystic duct is followed by absorption of the inflammatory product and hydrops of the vesicle. Acute catarrhal or suppurative cholecystitis may be followed by chronic empyema. Fistulas of all types may result from perforation into near by viscera or rupture may take place into the liver with the formation of an abscess cavity containing stones.

The kind and severity of the symptoms exhibited by the patient depend to a great extent on the degree of pericholecystitis present and on the degree of inflammation present in the rest of the biliary tract and pancreas.

Localization of the process is almost the rule even following perforation. The incidence of general peritonitis is low. Abscess in the liver rarely occurs even in suppurative conditions of the gallbladder except when it actually perforates into the hepatic tissue. Pylephlebitis with multiple abscesses is almost unknown. On the other hand, generalized non-suppurative infection of the liver or acute hepatitis is frequently seen. The liver is swollen and edematous and on microscopic examination reveals diffuse lymphocytic and polymorphonuclear leukocytic infiltration of the portal spaces. It is possible that the disease may be primary in the liver and secondary in the gallbladder. When the contents of the gallbladder are purulent or the organ has become gangrenous, it is unusual to find much infection in the pancreas. When this exists it may manifest itself as an apparently asymptomatic enlargement and hardening of the head of the gland in association with any degree of cholecystitis or it may occur as frank pancreatic necrosis. If pancreatitis is very marked or acute the patient will experience a much more severe pain which is usually in the same situation as the pain in most cases of cholecystitis; this pain may tend to localize deep in the epigastrium and to be projected through to the back. Fat necrosis about the pancreas may be found to a varying degree in these cases.

Symptomatology.—The symptoms in cases of acute cholecystitis are fairly well determined by the presence or absence of a stone obstructing the cystic duct. In the simple unobstructive type that frequently passes unrecognized as acute indigestion or

acute biliousness the onset is gradual and is ushered in by minor symptoms such as nausea, loss of appetite, a shivering attack and slight fever followed by indefinite aching pains in the epigastrium and right upper quadrant of the abdomen. Definite tenderness and rigidity of the right rectus muscle in the upper abdominal quadrant can be demonstrated and the pain slowly becomes more apparent but rarely requires morphine for relief. Occasionally it rises to the severity of colic if the inflammatory swelling of the mucosa is sufficient to occlude the cystic duct. With few exceptions such attacks subside under medical treatment.

Acute obstructive cholecystitis is characterized by a sudden attack of typical biliary colic which results from the passage of a stone down the cystic duct or its impaction in the neck of the gallbladder. Instead of passing off within a short time the colic changes to acute stabbing epigastric agony which is localized in the right subcostal region and is accentuated by the slightest movement of the diaphragm. Marked rigidity of the right rectus muscle and a slowly increasing area of tenderness over the gallbladder indicate the spread of pericholecystitis and involvement of the peritoneum in the inflammatory process. Vomiting and constipation are almost constant accompaniments. Chills may be severe but the temperature rarely rises above 101° to 102° F. The pulse is not diagnostic and the rate is usually proportional to the amount of fever present. Leukocytosis of moderate degree may accompany the condition although in more than 50 per cent of cases the leukocyte count will not be greater than 10,000. Jaundice in uncomplicated cases is not common and usually indicates involvement of the ducts when it does occur. This point is not generally appreciated but is of the greatest importance. A palpable mass in the right upper abdominal quadrant is present in about 90 per cent of cases. In a series of 508 cases studied by Judd and Phillips 484 patients had cholelithiasis and 43 had choledocholithiasis.

A conscientious perusal of the past history may be a great aid in establishing a diagnosis of acute cholecystic disease in a case in which there are definite pathologic changes in the upper portion of the abdomen. If

there has been a history of typhoid fever or repeated attacks of colic of the type associated with gallstones it is reasonable to assume that the gallbladder is very likely the seat of the trouble. However one must distinguish acute disease of the gallbladder from perforated peptic ulcer, acute intestinal obstruction, acute appendicitis, pathologic changes in and adjacent to the right kidney, acute infection in the right lobe of the liver and even coronary disease.

Treatment.—In the treatment of acute cholecystic disease there are two very definite trends of thought. It is conceded that in many acute abdominal conditions it is safer to operate when the acute symptoms have abated rather than when the attack is at its height. Some very competent surgeons subscribe to this view in dealing with acute cholecystic disease.

There are so many variable factors involved in a consideration of acute cholecystitis that it often is difficult to tell not only the time of onset of the acute attack but also the duration of the acute phase. One of the most interesting features in the study of disease of the gallbladder is the inability frequently to correlate the pathologic findings with evidence obtained by careful clinical examination of the patient. It is well known that after the acute clinical signs in the right upper abdominal quadrant have subsided and when the pulse rate and temperature have returned to normal the gross and histologic picture may remain that of acute cholecystitis. If early operation is interpreted as operation performed within a few hours after the onset of the acute attack, as nearly as the time of onset can be determined it will be noted that the tendency is more toward early surgical intervention. Two reasons have been advanced in support of early operation: (1) Operative procedure is facilitated if the operation takes place before marked evidences of pericholecystic and pericholecdochal inflammation have developed and (2) by early operation a possible diagnostic error whereby an acute inflammatory process in the appendix might be allowed to progress owing to the impression that the acute inflammatory process was in the gallbladder is obviated.

In a case of this type the surgeon frequently does not have the opportunity to

observe the patient until many hours or even days have elapsed after the onset of the disease. Under such circumstances the most satisfactory policy in most instances has been to allow the acute process to subside for three or four days with the patient under careful observation and during this time to pay particular attention to the patient's local and febrile reactions and to the degree of infection as suggested by repeated leukocyte counts, the Schilling count and the sedimentation rate of erythrocytes. The last named phenomenon has been found to be of great value because after all other signs and symptoms have disappeared an elevated sedimentation rate of erythrocytes may continue for some time to indicate persistence of the inflammatory process.

Operations for acute cholecystitis may be exceedingly difficult because of the existence of such complications as perforation of the gallbladder, the formation of an abscess or adhesions or the establishment of a fistula between adjacent viscera. When the duodenum becomes adherent to the gallbladder or the cystic duct and particularly when a cholecystoduodenal fistula results the operation may be extremely tedious. Difficulty is commonly encountered in separating and in closing the duodenum satisfactorily. In the event that an external duodenal fistula does form a rather serious postoperative complication is presented. If the fistula is small it may close spontaneously. A large one is usually so long in healing and so debilitating that operative intervention becomes advisable even though the risk is exceedingly great.

If acute cholecystitis is associated with biliary cirrhosis and jaundice the gallbladder is usually small and in some instances its function will be completely or almost completely destroyed. Obviously the inflammation in the viscus itself is then of secondary importance to that in the ducts and other hepatic tissues. The serious import of jaundice is well known. An effort should be made to decrease the jaundice before operating. The aim of the surgical procedure should be to reestablish the biliary intestinal continuity by the quickest and safest method. If stones are removed and drainage is established the gallbladder may be left for a subsequent operation although many

times the risk is no greater if cholecystectomy is performed at once and a secondary operation is avoided. Should there be diffuse inflammatory enlargement of the pancreas (pancreatitis) without obvious fat necrosis the best plan is to remove the gallbladder if this can be accomplished satisfactorily and establish drainage of the common bile duct by the use of a T tube. Many times it is difficult to determine whether the lesion in the pancreas is inflammatory or malignant. If there is any reason to suspect that there is a malignant condition in the head of the pancreas cholecystostomy should be performed or the gallbladder should be anastomosed to the stomach or duodenum. Although pancreatitis subsides more readily after removal of the gallbladder nevertheless biliary drainage will be efficacious if the lesion proves to be benign. Should it be malignant further palliative relief will be obtainable in some instances for the preservation of the gallbladder *in situ* will then permit the performance of a cholecystogastrostomy for diversion of the biliary secretions into the gastrointestinal tract. With associated fat necrosis the situation is serious but in many instances cholecystostomy and drainage of the pancreatic region have been helpful. In cases of extensive involvement of the pancreas any intervention should be confined to the relief of tension in the pancreatic tissues.

The consensus is that an acutely inflamed gallbladder should be removed if the procedure does not impose an unwarranted risk. One is confronted with an occasional case however in which institution of drainage seems advisable because the gallbladder is badly diseased and there is a great inflammatory reaction along the cystic and the common bile ducts or because the patient is a poor risk owing to age or illness. The decision to remove or to drain an acutely inflamed gallbladder rests on many factors in the individual case and an arbitrary rule of conduct cannot and should not be formulated.

CHRONIC CHOLECYSTITIS

Exactly what constitutes chronic cholecystic disease is in many instances a very debatable point. Obviously if calculi are present or if the wall of the gallbladder is grossly affected there can be little doubt re-

garding the process but there are many occasions when there is only a slight variation in the gross appearance of the gallbladder and when the clinical picture is certainly indicative of disease of the gallbladder out of all proportion to the appearance of the organ itself. Most of these cases will reveal some chronic change of tissue in the wall of the gallbladder detectable by careful microscopic examination. However these changes still may not appear adequate to explain the clinical syndrome and it is in these cases that cholecystectomy may give remarkably good or poor results without any clear explanation as to why the patient was or was not benefited by the procedure. In

many instances the characteristics of more than a single type may be observed. In a classification that seems to be of some practical significance the following are recognized: (1) chronic cholecystic disease due to infection (true chronic cholecystitis), (2) chronic metabolic cholecystic disease (cholesterosis of the gallbladder) and (3) clinical cholecystic disease without obvious pathologic change in the gallbladder.

Infection may reach the gallbladder in various manners. (1) Bacteria excreted by the liver may be carried in the bile to the gallbladder by means of the hepatic and cystic ducts. (2) Infection may ascend from the duodenum by way of the common bile

Fig. 594.—Large smooth-walled gallbladder (lymphoma). The adjacent hepatic tissue is normal in appearance.

those cases in which the patient is relieved it is assumed that cholecystectomy effected some change in the rest of the biliary tract. In those cases in which the patient is not relieved it is probable that there is a low grade chronic infection throughout the entire biliary tree and liver which was not affected by removal of one small link in the chain. The gallbladder may be almost completely destroyed by disease and yet produce few if any symptoms. On the other hand a very slight change in the tissues of the gallbladder may be accompanied by very pronounced symptoms.

Three well defined types of chronic cholecystic disease are recognizable although in

duct. (3) Infection may take place by direct extension of contiguous inflammatory processes from some adjacent organ such as the duodenum or colon and (4) lymphatic structures and the blood stream may act as conveyors of the bacteria. For a long time it was thought that infection originated from organisms in the bile. It is now almost universally believed that infection is usually hematogenous. The work of Rowen suggests that certain organisms chiefly streptococci have a selective affinity for the gallbladder and that they may come from any chronic focus of infection in the teeth, tonsils or prostate gland. In this connection it is well to remember that when once the gall

Fig 595.—Thick walled fibrous gallbladder with evidence of a lesion to abdominal viscera (extensive chronic cholecystitis). The liver appears normal.

Fig 596.—Marked degree of hepatitis of the right lobe. The gallbladder is small.

bladder is infected it in turn may become a focus. Thus removal of an infected gall bladder may be followed by subsidence of symptoms of arthritis and neuritis. How

ever it is often impossible to recover organisms from the gallbladder in which there is definite histologic evidence of infection. Positive cultures are more often obtained

Fig 397—Large gallbladder with markedly thickened fibrous wall (chronic empyema) There is some associated hepatitis

Fig 398—Extensive inflammatory disease of the gallbladder causing adhesion to the abdominal wall The liver is small and atrophic

from the wall of the gallbladder than from the stones or bile therein. The bile gives positive results in about 7 per cent, stones in 10 per cent and the wall of the gallblad-

der in 49 per cent of cases. A. L. Wilkie obtained positive cultures from the gallbladder in 86 per cent of a series of cases of chronic cholecystitis. The invading organ

ism in most instances is the streptococcus but the colon bacillus typhoid bacillus Welch's bacillus and others have been found. In fact it is probable that in most cases not only the wall of the gallbladder is involved but also the liver the bile ducts and frequently the pancreas.

The pathologic picture of chronic infectious cholecystic disease varies within wide limits depending on the duration and virulence of the infection the presence or absence of stones and whether or not the cystic duct remains patent (Figs 594 to 598). In most instances it is probable that the infectious process is more or less chronic and of low grade from the onset. In some cases the sequelae of acute inflammation will be present. Acute exacerbations of infection occur in chronically infected gallbladders especially if the cystic duct becomes obstructed. The first noticeable change is thickening of the wall of the gallbladder and an abundance of fibrous tissue displacement. The mucosa may be hypertrophic atrophic ulcerated or completely destroyed. There may be extensive infiltration of the remaining coats of the wall with round cells and an abundance of fibrous tissue. The serosa loses its glossy appearance and frequently becomes adherent to surrounding structures. The lymph nodes along the cystic and common bile ducts are usually enlarged. In many instances gallstones are found within the lumen of the gallbladder. Although it is probable that infection is the most constant primary factor in the production of gallstones there are undoubtedly cases in which stones precede infection and the etiology of the cholelithiasis must be explained on the basis of an altered metabolism. If the cystic duct becomes obstructed because of infection or because of impaction of a stone hydrops of the gallbladder often results and the viscus may reach an enormous size. In such instances the content is usually a clear colorless mucus but empyema is not an uncommon occurrence. Perforation is more common in a gallbladder that is involved in an acute infectious process than in one in which the infection is of the chronic type. However when perforation does occur with the latter it is usually into an adherent omentum or some viscus such as the duodenum colon liver or stomach.

Chronic metabolic disturbances are the basis of another type of cholecystic disease. Frequently signs of inflammation are absent from a gallbladder that contains stones of pure cholesterol although the patient presents all the characteristic symptoms of cholecystic disease. A causative factor in the formation of the stones apparently is disturbance in the metabolism of cholesterol the exact nature of which is not completely understood although cholesterosis of the gallbladder seems to play a part. In many reviews are reported clinical cures following removal of gallbladders of the strawberry type without stones. This would seem to indicate that removal of this one link from the chain of disturbed metabolism of cholesterol stops the process and allows a return to normal.

To admit that clinical cholecystic disease exists without obvious pathologic change in the gallbladder probably is a confession of lack of knowledge concerning the underlying disturbed physiologic processes of the biliary tract. There is on occasional case however that prevents just such a problem. If the gallbladder is not removed symptoms will continue if cholecystectomy is performed the symptoms often will be relieved. Frequently there are a few small areas of cellular infiltration to support the diagnosis but this does not settle the question. Further investigation no doubt will throw light on this group of cases and may show that the primary trouble is hepatitis and cholangitis in which the gallbladder is playing only a part. At present the decision for or against removal of the gallbladder must depend on a careful scrutiny of the clinical history. Thus from a practical standpoint in cases of this type the clinical history is of greater importance than the roentgenologic data or the gross pathologic picture at the time of opening the abdomen. Present surgical procedures must be based on these practical considerations.

Symptomatology.—The symptoms of chronic cholecystic disease may vary within wide limits depending on the severity of the condition and the sensitivity of the individual patient. Many gallstones apparently do not produce symptoms as they are often discovered during the general examination of patients who consider themselves per-

fectly well and they are found frequently at necropsy of subjects who had no complaints referable to the biliary tract. At the other extreme are patients with most severe biliary colic who are found at operation to have a minimum of pathologic change in the gallbladder.

The most characteristic symptom of chronic cholecystic disease is recurrence of attacks of biliary colic. This symptom when typical is pathognomonic of disease of the biliary tract. The pain characteristically begins more or less suddenly in the epigastrium or right upper quadrant of the abdomen and is projected around the right costal border to the right subscapular region. It is most severe and often requires repeated injections of morphine for relief. At the onset the patient frequently is nauseated and vomits. There is a picture of extreme distress which without a doubt establishes the fact that there is intense pain. The pain may cease as suddenly as it began after a few minutes or hours but the usual sequel is marked residual soreness in the region of the gallbladder for several days. The colic may or may not be recurrent and during the interval there may be entire freedom from all symptoms. The temperature usually remains normal or subnormal during the paroxysm and the pulse is accelerated. Most patients with chronic disease of the gallbladder will have at least one attack of biliary colic during the course of the disease. Many patients characterize their distress as a dull aching soreness under the right costal border which is made worse by jolting or jarring or by eating a full meal. In some cases the sensation is merely a feeling of fullness.

Digestive disturbances of one sort or another are present in most cases of chronic disease of the gallbladder. Epigastric fullness after meals with bloating and gaseous eructations is extremely common and may be the most troublesome feature of the disease. Certain patients will not tolerate fried or greasy foods and others coarse vegetables but many find that mere overloading of the stomach with any type of food seems to cause distress and may precipitate an attack of colic.

Jaundice is not a common accompaniment of chronic cholecystic disease if the

gallbladder alone is infected. However a large stone in the neck of the gallbladder may occlude the common bile duct by pressure. There may also be transient jaundice which is the result of associated hepatitis or cholangitis; this jaundice leaves as the attacks subside.

There may be little besides the information contained in the history on which to make a diagnosis of chronic cholecystic disease if the patient is seen sometime after the colic has subsided. As a rule however on careful palpation in the right upper quadrant of the abdomen there will be some tenderness to pressure as the margin of the liver moves down on deep inspiration. Occasionally if the gallbladder is extremely large owing to chronic obstruction of the cystic duct it can be felt as a rounded mass moving up and down freely with the liver during respirations. If the patient is seen during or immediately following an attack of colic there will be marked tenderness in the region of the gallbladder with rigidity of the overlying abdominal muscles.

A carefully taken clinical history is most important in the diagnosis of chronic disease of the gallbladder. If one or more of the foregoing symptoms have been elicited suspicion should be aroused. In the event one is not able to make a definite diagnosis the decision as to whether or not the condition requires surgical intervention is the paramount issue.

Cholecystography may prove an invaluable aid to a just decision if due consideration is given to the other available data including the history. Cholecystography is primarily a method of depicting a test of the concentrating ability of the gallbladder. The interpretation rests on the determination of the amount of variation from the normal density of the cystic shadow. Positive data regarding the degree of remaining function in the gallbladder are reliable in as high as 97 per cent of the cases; however with normally functioning gallbladders the chance of error is about 10 per cent. It is important to stress the point that cholecystography should not be relied on without clinical data to affirm or deny the presence of disease of the gallbladder. Cholecystographic findings may be of assistance in cases in which for one reason or another diagnosis has been

observed but all the evidence should be weighed concurrently in making the final decision. Of course when gallstones are visualized the diagnosis is made but the possibility of their presence in spite of negative cholecystographic findings makes it imperative never to lose sight of the fact that the essential point in the diagnosis may be a typical history alone.

Treatment—According to the present conception of chronic cholecystic disease some change in the wall of the gallbladder represents the seat of the trouble. The only way in which to eradicate the primary factor is to remove the organ. There are numerous records indicating that cholecystostomy has given permanent relief and occasionally in chronic cholecystic disease it may be indicated with the idea that it will later be followed by cholecystectomy but when all things are considered cholecystectomy is much more satisfactory. Furthermore chronic cholecystic disease in almost all cases is essentially a surgical problem and most certainly so if stones are present. The risk of operation early in the course of the disease is low and the disastrous sequelae of obstructive jaundice and extensive hepatitis justify the opinion that early surgical intervention is safest and wisest.

Usually the presence of stones in the gallbladder is sufficient to justify surgical exploration even if the patient does not complain of symptoms referable to the gallbladder. It is obvious that factors in the individual case will influence the surgeon's conduct in this matter. Frequently, varying degrees of inflammatory change may be observed in the liver and the pancreas in association with "symptomless gallstones." To remove the gallbladder in such a case may tend to protect the patient against the progression of the related disease and against the possibility of subsequent mechanical obstruction of the cystic or the common bile duct by a calculus.

The removal of the gallbladder is contra-indicated in certain cases and drainage is substituted. The condition under which cholecystostomy is preferable may be summarized as follows: (1) in the presence of local technical difficulties such as obesity which make it impossible to identify important structures; (2) if the general condi-

tion of the patient is such that cholecystectomy would be hazardous; (3) in some acute conditions of the gallbladder and liver; (4) in the presence of obstructive lesions of the common bile duct when relief from jaundice is the paramount issue and (5) when the character of obstruction of the common bile duct is such that cholecystogastrostomy may need to be performed later.

Cholecystostomy which is carried out because of inflammatory disease offers some chance of cure in itself. In one study it was found that approximately a fourth of the patients who had undergone cholecystostomy had persisting severe symptoms (about 50 per cent of these later submitted to cholecystectomy); a fourth had some mild symptoms and the remaining half had no distress referable to the biliary tract.

Occasionally cholecystostomy is performed although the procedure is usually far from satisfactory and has a very limited field in surgery. The inadvisability of removing stones and leaving the gallbladder is evident when one considers the probability that the infection is in the wall of the gallbladder. Furthermore suturing the gallbladder without draining it is a more hazardous and certainly a less efficacious procedure for prolonged drainage might at least be some aid in clearing up the inflammatory process. The thesis therefore that if the gallbladder can be saved it will resume its normal function is not well founded and certainly clinical experience indicates that in most cases cholecystectomy is the procedure of choice.

CHOLEDOCHOLITHIASIS

The symptoms arising from stones in the common bile or hepatic ducts are those indicative of cholecystic disease plus the added factor of jaundice. It is of course possible to have stones in the ducts without ensuing jaundice and if symptoms persist following a typical attack of acute biliary colic disturbances in the ducts should be suspected. The presence of jaundice depends on whether the calculus passes through the ampulla into the duodenum or becomes firmly impacted in the ampulla and acts as a ball valve at the lower end of the bile duct at times becoming dislodged and floating also in the bile stream. If obstruction is com-

plete the serum bilirubin will become fixed at from 20 to 30 mg per hundred cubic centimeter of blood. Usually if impaction is not constant the jaundice fluctuates for at times it is possible to have an ample flow of bile. Fluctuating jaundice and the presence of pain are the outstanding features that help to distinguish between obstruction due to a calculus and that due to a neoplasm although it should be remembered that pain is sometimes an early and persistent accompaniment of neoplastic growth. There are many cases in which the cause of jaundice cannot be determined until an exploratory operation is performed. In either case if obstruction is of long duration the injury to the liver will be great and not infrequently the condition will be terminated by an acute suppurative cholangitis.

The selection of the optimal time for operation in the presence of a marked degree of hepatic injury is of paramount importance for it is a factor in reducing the surgical mortality. Patients with obstruction of the biliary passages of considerable duration do not stand operative procedures well. Those with deep jaundice of short duration are better risks than those whose jaundice is less marked but has been of longer duration. An operation should not be undertaken when jaundice is fluctuating nor at a time when hemorrhagic tendencies are increasing. If fever is present it is wise to wait a reasonable time for the acute infection to subside. Dehydration and poor nutritional states can be relieved to an appreciable degree by restorative measures. When death occurs in these cases it is usually from hepatic and renal insufficiency.

Fortunately stones in the intrahepatic ducts are not common. However this possibility should be kept in mind considering the recurrence of stones after operation on the gallbladder and ducts. Calculi in the substance of the liver are rare. Intrahepatic stones may not be manifested by symptoms for years but occasionally the outcome of such a condition is the development of a serious suppurative cholangitis.

The history of jaundice or its presence should make examination of the common bile duct imperative. If much dilatation of the duct is found it should be opened and explored with a probe and a scoop but it

should be remembered that in the presence of a non functioning gallbladder the duct will be dilated. Removal of the gallbladder should be deferred until the lumen of the duct is proved to be sufficient for the viscous mass to be utilized advantageously for an anastomosis to the intestine to divert the flow of bile. With deep jaundice present it may be safer to institute drainage of the gallbladder than to perform cholecystectomy. Supraduodenal choledochotomy is the best means of removing calculi from the common bile and hepatic ducts.

Preoperative and Postoperative Treatment—The patient should be observed in the hospital for several days before operation. The three chief surgical complications to be kept in mind are hemorrhage, hepatic insufficiency and renal insufficiency.

The best method of protecting the patient against hemorrhage during and after operation is by administration of vitamin K. It has been well demonstrated that in patients who have obstructive jaundice from any cause, biliary fistula or mild hepatic damage there may develop a tendency to hemorrhage. In most instances this tendency can be corrected by the proper administration intramuscularly, intravenously or by mouth of vitamin K in the form of synthetic compounds. It is a wise precaution to give vitamin K for one or two days prior to any type of operation performed on the biliary tract regardless of whether or not the patient is jaundiced. Of the synthetic compounds 1 to 2 mg daily for one two or three days administered by mouth together with 10 to 15 grains of animal bile salts seems to be an adequate dosage or 1 to 2 mg administered by the intramuscular or the intravenous route without bile salts is sufficient. At times it may be necessary to administer vitamin K at the operating table especially in cases of jaundice or hepatic injury if hemorrhagic oozing begins. The patient should receive vitamin K after surgical operation for at least four or five days and the prothrombin clotting time should be followed carefully for at least another five days. Any rise in the prothrombin clotting time calls for further administration of vitamin K.

Occasionally patients who from one cause or another have severe hepatic parenchymal

damage must be subjected to surgical operation. Frequently the prothrombin clotting time is elevated and will not respond to the administration of vitamin K. In our experience and in the experience of many others this phenomenon often indicates that the liver is damaged rather badly. In spite of failure of response in the prothrombin clotting time the patient should receive the same type of preoperative and postoperative treatment with vitamin K as if response had occurred and if hemorrhage takes place transfusions can be employed. After surgical operation in a case in which response to the administration of vitamin K has failed to take place the surgeon should observe the patient carefully for symptoms of impending hepatic coma which sometimes results in cases of this type.

Calcium chloride also has been used intravenously to increase coagulability of the blood but just what part it plays in this respect is not clearly understood. Since an injured liver can utilize carbohydrates more readily than other nutrient substances large quantities of a 10 per cent solution of glucose are administered intravenously either alone or combined with a 1 per cent saline or a 2 per cent solution of sodium γ lactate. The role of sodium γ lactate is not definitely known but in some instances it seems to aid in restoring hepatic function. These measures are further supplemented by prescribing a diet high in carbohydrates. The increased intake of fluid just described serves a double purpose in the presence of jaundice for it is also excellent treatment for a coexisting toxic nephrosis.

Postoperatively carbohydrates are given in abundance and intravenous glucose solutions are continued as before operation. The administration of oxygen by the tent method or by nasal catheter is frequently of value if there is any evidence of a pulmonary complication.

CHOLECYSTOSTOMY

The essential requirement of an incision for operation on the gallbladder or bile ducts is that it must be properly placed. When this is accomplished the incision facilitates the necessary exploratory procedures and reduces the liability of ensuing hernia. The best exposure is obtained by making the incision from the right side of the ensiform

notch obliquely downward to a point 4 cm to the right of the umbilicus. The anterior sheath of the rectus muscle is divided in the same line as the skin and the right rectus muscle is retracted laterally after being freed from its sheath on the mesial side. The posterior sheath of the rectus muscle and peritoneum are then opened about 1 or 2 cm from the median line. Better exposure of the biliary tract is obtained by incising the peritoneum as high as possible toward the thorax rather than by extending the incision downward. Clamping and cutting the suspensory ligament of the liver is often ad-

Fig 599—*a* Gallbladder grasped with two forceps. A large scoop is pressed against the external surface as an aid in emptying the vesicles and catches its contents. *b* Incisions made in the gallbladder.

vantageous in bringing the biliary tract into view.

The technique of performing cholecystostomy varies somewhat according to whether the organ is markedly distended with bile but is free from inflammatory changes or whether it is thick walled and contracted and contains stones. In the former case the patient is usually deeply jaundiced and the obstructive lesion lies in the head of the pancreas. Here the main object of the operation is to relieve the jaundice with as little risk of hemorrhage as possible. It may be the only operation considered necessary or it may be preliminary to the cholecystogastrostomy. If the gallbladder is thick

walled and contracted and contains stones, the operative field is packed off and the fundus of the gallbladder is held in the grip of two curved clamps and elevated well up into the field. The content of the organ is aspirated by means of a trocar. The fundus is then opened with scissors, and curved forceps are re-applied to the edges about the opening. The contents of the gallbladder are then removed with a scoop. A large scoop is pressed against the external surface of the viscus, at the level of its neck, to catch any overflow of bile or stones (Fig. 599). When

The wound is closed without fastening the fundus to the peritoncum. A split tube is placed outside the gallbladder (Fig. 601).

Fig. 600—*a*, A dressed tube is placed in the gallbladder; *b*, purse string sutures are placed about the tube, *c*, a second row of inverting sutures is employed

the gallbladder has been entirely emptied, a dressed rubber tube, consisting of a central core of heavy rubber tubing with a bore of 1 cm wrapped in gauze and surrounded by a Penrose drain, is placed in the gallbladder so that it projects almost to its neck. A rubber catheter may be substituted for the dressed tube, although this usually is not as satisfactory. The fundus is then closed with a purse string suture (Fig. 600), and the dressed tube is tightly anchored to the wall of the gallbladder by passing the suture through it at one point. Usually a second purse string suture is placed above the first.

Fig. 601—Operation completed. The split tube is placed beside the gallbladder

CHOLECYSTECTOMY

Removal of the gallbladder is the procedure most frequently indicated in the presence of: (1) subacute or chronic cholecystitis with or without stones, (2) chronic empyema, distention or hydrops of the gallbladder due to blockage of the cystic duct by a calculus, stricture, neoplasm or external inflammatory deposit, (3) gangrene of the viscus itself, (4) pancreatitis in association with disease of the gallbladder if only slight jaundice is present, (5) calcareous degeneration of the gallbladder, (6) cholelithiasis of the gallbladder, (7) primary benign or malignant tumor confined to the gallbladder and (8) clinical cholecystitis, that is, until the true nature of the disturbed physiologic process in this last condition is better understood. Of course if there is an obstructive lesion in the common bile duct and its satisfactory removal is problematic, the gallbladder should be left in situ, if possible, as it will often prove useful in restoring biliary-intestinal continuity. Cholecystectomy will accomplish a great deal toward the relief of the pancreatitis which is so often found in association with disease of the gallbladder, but in many in-

stances prolonged drainage of the common bile duct should also be maintained

Although there is not a direct relationship between cholecystic disease and coronary disease in certain types of cases however those in which colics recur those in which cholecystic disease has impaired digestion so that the general condition has suffered and those in which flatulence has existed or in which the patients have been very ill either from jaundice or from toxic states removal of the gallbladder has resulted in improvement in the general con-

dition and thereby be mistaken for the cystic duct In about 7 per cent of cases there is some variation from normal in the arrangement of the biliary ducts the hepatic artery or the cystic artery It is therefore highly important to identify the cystic duct and artery positively before they are ligated or cut If the situation of these structures has been ascertained there is no objection to ligating them together Part of the success of the operation depends on the proper placing of moist gauze packs for the exclusion of other intra abdominal organs from

Fig 602—The common and cystic bile ducts visualized The cystic duct is clamped with the forceps

dition and consequently in direct betterment of the cardiac condition

The incision is made in the same way as for cholecystostomy Adhesions should be separated carefully before proceeding further every effort being made not to injure large blood vessels which may retract into fatty tissues and later produce hematoma Before anything more is done the common bile duct should be identified and exposed Usually injury to this duct results from efforts to control bleeding from the cystic artery It may also result from clamping the cystic duct too near the common bile duct or the common bile duct may be strangulated from too much tension on the

the operative site Frank hemorrhage from the cystic artery and injury to the common bile duct are the two great dangers in performing cholecystectomy Cholecystectomy will not only be easier but safer if it is begun at the cystic duct since the circulation will be controlled at the outset

With the left hand the assistant exposes the operative field mesially another assistant rotates the liver into the wound and holds it there by making traction on the suspensory ligament and lateral traction on the right edge of the wound Dissection of the cystic duct is then commenced When the body of the gallbladder overlies and is adherent to the common bile duct it must be

separated with great care. The peritoneum is then incised and by means of blunt dissection the cystic duct is cleared and isolated from the fat that surrounds it. A curved forceps is passed from below so that the beak projects between the duct and the cystic artery. After 2 cm of the cystic duct have been exposed by separating the blades the duct is caught by two narrow bladed 7 inch clamps and divided either by knife or

clamp which has been used to close the cut end of the duct. An edge of peritoneum is left on each side of the fossa of the gall bladder to facilitate subsequent suture. Before the gall bladder is entirely removed from the liver the stump of the cystic duct is doubly ligated with no. 1 chromic catgut and the cystic artery is securely tied with the same material (Fig 604). The gall bladder is then quickly removed in closure

Fig 603—The cystic duct is clamped and the gallbladder being dissected from the cystic duct upward. The cystic artery is clamped.

scissors (Fig 605). The two ends are immediately touched with a solution of iodine. The lower clamp should be at least 2 cm from the common bile duct so that sufficient room is left to apply the ligature. Next the cystic artery is separated in the same manner and divided. If another branch should be present it is treated similarly. The gall bladder is then pulled from the liver in the plane of cleavage (Fig 603) which is easily demonstrated by maintaining tension on the

of the region is made by a continuous suture (Fig 605) commencing at the point at which dissection of the gallbladder was begun. Care should be taken not to include or strangulate any hepatic tissue in this suture. The suture is carried to the inferior margin of the liver where it is tied and cut. Closure of the wound without drainage is a perfectly safe procedure if the surgeon is certain that the cystic duct and artery have been securely tied if the fossa of the gallbladder

Fig 604.—The cystic duct is doubly ligated, and the cystic artery is caught in a stitch suture.

Fig 605.—Suture used to peritonize the cholecystic fossa.

has been carefully sutured and if the operative field is dry Drainage is imperative in cases in which there is active infection or leakage of bile The presence of half of a rubber tube drain does not add to the risk of development of hernia, provided the tube is brought out high up in the wound under these circumstances it does insure a safer convalescence

CHOLEDOCHOSTOMY

The experienced surgeon is justified in performing choledochostomy if there is a history or evidence of obstruction of the common bile duct and even in the absence of symptoms if the duct is found to be enlarged Obstruction that is the result of a malignant growth is a separate problem Usually a growth of sufficient size to cause obstruction to the flow of bile through the common bile duct can be diagnosed as such by palpation The gallbladder should never be removed until the necessary treatment of the common and hepatic ducts has been effectively carried out (Figs 606 and 607)

After exposure of the common bile duct the anterior wall is elevated by grasping it with two Allis forceps about 0.5 cm apart and a longitudinal incision is made between the two instruments If the duct is sufficiently dilated the incision should be large enough to admit the examining finger However if a stone can be palpated in the common bile duct before it is opened the incision can be made directly over the stone by grasping the duct and fixing the calculus between the thumb and finger of the left hand Then after removal of the calculus other loose debris can be sponged scooped or washed out of the duct The adjacent structures should be manipulated no more than is absolutely necessary in order to preclude injury to the portal vein or the hepatic artery

When the common bile duct is explored for any reason immediate closure of the opening is usually not advisable for in most instances in which cholecystitis is indicated cholangitis is present which is best treated by free drainage of the biliary tract The extent of the disease is the important factor in judging the length of time drainage should be maintained A Kehr-Dewey T tube is preferable for this purpose but

should there be only a mild degree of cholangitis cirrhosis or pancreatitis the use of an ordinary catheter in the duct may suffice However the advantages gained by using a T tube are (1) The tube will remain in place as long as it is required and can be removed with ease (2) the flow of bile can be controlled by clamping the tube (3) irrigation of the ducts can be instituted and (4) fluids can be introduced into the duodenum for feeding purposes when required As far as can be determined there has not been a tendency toward stricture of the common bile duct as a result of pro-

Fig. 606—A palpable stone in the common bile duct is being grasped between the fingers. The incision was made directly over the stone.

longed contact with a rubber drainage tube The ordinary catheter will fall out of its own accord in about nine or ten days but steady traction must be applied on a T tube before it can be removed In either instance the resulting biliary fistula is prompt in healing

As has been shown frequently much information in regard to the patency of the common bile duct can be obtained by injecting radiopaque oil through the T tube and following its course by means of the

Fig. 60—*a* The incision in the common bile duct is left open by Allis forceps and the proximal end of the T tube is inserted *b* the distal end of the T tube is placed in the common duct *c* the opening in the common duct is closed by continuous suture over the arms of the T tube *d* the common duct is closed snugly about the T tube which emerges from the upper end of the incision in the duct

regulating mechanism of the biliary tract may account for some of the symptoms that occur or persist after cholecystectomy for it has been shown experimentally that under certain conditions there is an increase in the pressure in the common duct after the removal of the gallbladder. A gallbladder which has undergone pathologic change may still be able partially to regulate the intraductal pressure but if this function of the viscus is completely lost as a result of rather gradual progress of the process finally terminating in extensive disease there will be compensatory dilatation of the common bile duct. When a normally functioning or partially functioning gallbladder with or without stones is removed an imbalance in pressure is produced immediately. This may explain why some patients continue to have colic for a short time after cholecystectomy. Disturbances of this type will persist only until the tension becomes sufficient to produce dilatation and finally overpower the sphincter. Evidently in some instances the sphincter is not easily dilated and has a tendency to be spastic. This situation is particularly frequent among high strung persons who are also likely to have an irritable bowel.

Colic following cholecystectomy not due to stone always presents a difficult problem. The attacks of colic are usually the result of persisting infection in the tissues and they decrease in severity as the infection subsides. Before any secondary surgical procedure is performed sufficient time should be allowed to elapse to make certain that the symptoms will not cease spontaneously. Meanwhile such conservative measures as a regulated diet and duodenal drainage often prove efficacious. Magnesium sulfate may be introduced through the duodenal tube for the purpose of lowering the sphincteric tonus. Occasionally the colic is wholly the result of dietary indiscretions. Partially neuralgic renal and gastric colic or angina pectoris may be responsible for symptoms that seem to be referable to the biliary tract and so the difficulty of making a clear-cut preoperative clinical diagnosis is increased. The possibility of the existence of an ulcer in the duodenum should always be carefully considered. A clinical diagnosis of stone in the common duct is likely to be made erroneously. Jaundice or persistent severe in-

termittent colicky pain should be included in the indications for the second operation or many patients with functional disturbances will be subjected to abdominal operations that are predestined to be fruitless.

If an exploratory operation is carried out and the presence of a stone is not demonstrated it becomes necessary to search elsewhere for the cause of the disturbance and to determine whether there is any change in the pancreas, liver or ducts. Occasionally an ulcer on the posterior wall of the duodenum will give symptoms which are indistinguishable from those of disease in the biliary tract although roentgenologic investigation of the stomach and duodenum has not revealed the presence of a lesion. The frequency with which secondary operation is required for colic following cholecystectomy may be estimated from the fact that in a five year period during which cholecystectomy was performed 4201 times there were only 39 patients with symptoms of such severity that secondary exploration of the ducts was justifiable because of colic that was not due to a stone.

Prolonged drainage of the biliary tract by the use of a T tube is the procedure of choice in the event surgical intervention is required because of colic following cholecystectomy. Ordinarily the tube should be allowed to remain in place for from three months to a year depending on the extent of the disease. Sometimes emergencies arise which make it difficult to keep the tube *in situ* for a period deemed adequate for relief. It is unreasonable to expect free drainage of the biliary tract for a few days or two or three weeks to relieve a condition that has been developing for several years. Sometimes because of underlying pathologic changes that have created irreparable injury it is impossible to improve conditions by any known means.

Before removing the tube from the duct it is advantageous to make a study of the biliary tree. This can be done by injecting radiopaque oil through the tube. The patient is placed under the fluoroscope so that the passage of the medium through the biliary tract can be observed. This makes it possible to obtain a better understanding of the biliary tract especially as to the patency of the ducts.

The T drain is removed by gentle traction on the long arm of the tube. In most instances anesthesia will not be required for this procedure although occasionally it will be advisable to give a few whiffs of gas to the patient who is nervous or high strung. If the ducts are patent there will usually be no external drainage after removal of the tube; the opening in the duct usually heals quite promptly. Not infrequently patients living at a distance are able to return home twenty-four hours later.

On a few occasions paravertebral injection of novocain has been used for the relief of severe recurring colic. This was done on the basis that in the experimental animal dilatation of the cystic duct is accompanied by marked inhibition of respiration vomiting struggling and other evidences of pain and that these responses were abolished by section of the right splanchnic nerve. This procedure or section of the rami communicantes with removal of the posterior root ganglion will be justifiable in a few cases in which paravertebral injection with novocain is unavailing and in which recurring attacks of severe intractable biliary colic which do not have a clear etiologic or pathologic explanation continue. Rarely one is confronted with a patient in whose treatment all the above procedures prove ineffectual. Under extreme circumstances transduodenal approach to the major papilla and a plastic operation on the sphincter of Oddi may be necessary. Transplantation of the common bile duct has been done in order to permit free biliary drainage without obstruction owing to a spastic condition of the biliary sphincter. The immediate risk of this procedure does not justify its utilization unless all other measures have failed and unless the patient's symptoms are such that he is unwilling to endure them longer.

SUMMARY AND COMMENT

From a therapeutic standpoint the gall bladder may be said to be the mischief maker of the biliary system for its removal when diseased usually brings about remedy or cure. Relief follows cholecystectomy not only because of removal of the diseased gall bladder but also because of the physiologic changes brought about in the biliary tract

that permit spontaneous recovery from an infection remaining in the regional tissues. However numerous studies have revealed that from 2 to 10 per cent of patients with definite gross lesions in the biliary tract are not relieved by operation and that this is largely due to cholangitis hepatitis and pancreatitis which fail to subside following extirpation of the gallbladder. Gross indiscretions in diet may also be an important factor. It must be remembered however that benign unrelated lesions may be responsible for recurrent symptoms. Hemolytic jaundice is an occasional accompaniment of gallstones and of course fails to disappear following their removal. Carcinoma of the ducts or gallbladder may develop shortly after operation but presumably this is purely coincidental. Finally parietal neuralgia renal and gastric colic and angina pectoris may be responsible for symptoms that seem to be referable to the biliary tract.

If attacks of severe colic following cholecystectomy continue to occur regardless of carefully planned conservative treatment which has been carried out for a reasonable period of time the cause of such attacks is most likely to be (1) insufficient drainage of the biliary tract at the time of previous operation (2) a stone in the duct that was overlooked at the operation (3) a calculus formed subsequently and (4) traumatic lesions of the ducts and adhesions although the last should not be incriminated until all other causes are eliminated including the possibility that the original diagnosis was not correct. Fortunately stricture of the ducts from trauma during the cholecystectomy is not as common a cause of failure as other conditions but when this does occur it offers formidable problems. Deaver has emphasized two other factors that lead to poor results (1) long standing and extensive inflammatory lesions of the biliary tract which have caused irreparable injury to other organs such as the liver pancreas and heart and (2) lack of ability on the part of the surgeon to select the type of operation best suited to the lesion that is present in the biliary system. If severe attacks of colic following cholecystectomy continue to occur it may be necessary to establish prolonged drainage of the biliary

tract through the insertion of a T tube into the common bile duct in order to obtain control of the situation. In some instances because of persistence of infection or reformation of calculous debris and recurrence of symptoms it may be found to be imperative to perform choledochostomy a second time.

An operation can be held responsible for improvement in a patient's condition only if the improvement persists for a reasonable period of time or if it becomes permanent. Complete removal of stones from the biliary tract, the extirpation of a markedly diseased gallbladder or the skillful performance of any required procedure should afford relief from the more severe symptoms and should eventually result in cure in a high percentage of cases. Substitution of cholecystectomy for choledochostomy whenever possible would result in the greatest single reduction in the number of secondary operations required in the biliary tract. The relief obtained by cholecystectomy in cases of clinical cholecystitis seems to be in definite ratio to the severity of the pain and other symptoms characteristic of cholecystitis. If the history indicates that there has been dyspepsia of obscure origin particularly without pain but associated with neurosis, nervous exhaustion or migraine the chances of cure following removal of the gallbladder are poor. Making allowances for individual interpretations of what constitutes a good or a fair result, however, it is found that 80 per cent of the patients with definite disease in the biliary tract will be relieved of their symptoms if the proper treatment is carried out and the condition of an additional 10 per cent should be definitely improved.

F. STAHN, M.D.

Revised by HOWARD K. GRAY

Papillomas—Most of the benign tumors are papillomas but all except a few of these consist merely of hyperplastic villi which are laden with cholesterol esters and not cholesterol itself (Boyd). In this respect they resemble the hyperplasia of villi occurring in the strawberry gallbladder which has been described by Movshian and MacCarty. This type of papilloma is small (1 to 5 mm in diameter) and frequently multiple. It appears that infection and metabolic disturbances are the etiologic factors in the development of the tumors. MacCarty encountered this type of tumor in 4 per cent of 5000 gallbladders removed at the Mayo Clinic. There are two other types of papillomas, each of which is exceedingly rare. One of these is a soft waxy friable mass which may fill the entire gallbladder while the other appears to have a more solid base with small papillae covering the surface in a way which gives the tumor a cauliflower-like appearance (Henry). There does not appear to be any relation between these papillomas and carcinomas of the gallbladder except that papillomas may on rare occasions be precursors of carcinomatous growths.

Adenomas—This type of tumor is less commonly encountered than papillomas. Wellbrock found 69 instances in 9550 gallbladders removed at the Mayo Clinic. All but 4 were located in the fundus and 2 of them were malignant. Characteristically they are small nodules (1 to 10 mm in diameter) which are palpable in the wall of the gallbladder but protrude beyond the level of the mucosa. In his series Wellbrock excluded the cystic and papillomatous tumors and included only those with glandular structures within the wall of the gallbladder.

of Benign Tumors.—It is quite clear that none of the benign tu-

Kirklin has been able to diagnose them by cholecystography provided of course a shadow of the gallbladder has been obtained. It is a significant and somewhat unexplainable fact that most benign tumors although they accompany cholecystitis are rarely found in a gallbladder which is badly diseased.

Treatment—The treatment of benign tumors of the gallbladder is not a very significant feature since few of them produce symptoms. The tumors are of course eliminated by cholecystectomy which is indicated perhaps because of the symptoms produced by the accompanying cholecystitis. It is obvious that on rare occasions when vague dyspeptic symptoms are present along with a gallbladder which appears to be functioning quite normally from the cholecystographic standpoint the demonstration of a benign tumor by cholecystography would be sufficient to justify cholecystectomy.

MALIGNANT TUMORS OF THE GALLBLADDER

Studies made by Kaufman many years ago revealed that about 5 per cent of all carcinomas encountered at autopsy were located in the gallbladder. Several years later Lam reported that U. S. vital statistics for 1936 revealed an incidence of 4.5 per cent. The writer would prophesy that now (1945) the incidence of carcinoma of the gallbladder in the total group of carcinomas would show a further decline because (1) gallstones are being removed earlier than they were twenty-five or thirty years ago and (2) the incidence of some other carcinomas notably carcinoma of the lung has increased markedly in the last decade. Carcinoma of the gallbladder is encountered three or four times more frequently in women than in men. Statistics vary considerably as to the incidence of gallstones in primary carcinoma of the gallbladder (50 to 100 per cent). The average of ten large series reported recently was 78 per cent.

The importance of cholelithiasis in the development of carcinoma of the gallbladder can be more readily appreciated when the fact is considered that from 4 to 14 per cent (Rollston and McNeely) of all cases of cholelithiasis are associated with carcinoma. In 12.3 per cent of 592 cases of gall

stones encountered at autopsy Fawcett and Rippmann found that carcinoma of the gallbladder was present. Graham and associates found that at Barnes Hospital 8.5 per cent of all proved cases of cholelithiasis (operation or necropsy) were associated with carcinoma of the gallbladder or bile ducts. In only 2 per cent of over 15,000 cases of cholelithiasis reported by Judd and Gray was carcinoma of the gallbladder or bile ducts (as demonstrated by operation) present. From these figures it is obvious that there is considerable discrepancy in the incidence of carcinoma of the gallbladder in cholelithiasis. However the writer is of the opinion that a figure of between 4 and 5 per cent arrived at by Mohardt after a study of innumerable reports represents a fairly accurate estimation of the incidence of carcinoma in cholelithiasis. This corresponds closely to a recent series of 13,330 autopsies reported by Kirschbaum and Kozoll who found carcinoma of the gallbladder or extrahepatic bile ducts in 4.9 per cent of bodies revealing cholelithiasis. The incidence of carcinoma of the gallbladder or bile ducts in cholelithiasis should of course be higher in an autopsy series than in a series of operations since the patients in the latter series will be younger.

In summarizing the clinical importance of the relation of carcinoma of the gallbladder to cholelithiasis it appears safe to conclude that cholecystectomy as a prophylactic against carcinoma of the gallbladder is not a justifiable procedure. However numerous borderline cases will be encountered to which symptoms are so mild that a decision as to advisability of operation will be difficult to make. In this group it appears justifiable to allow the danger of development of carcinoma to influence one in recommending cholecystectomy particularly if the life expectancy of the patient still extends over a period of many years.

Pathology—Ewing has classified carcinomas of the gallbladder grossly into (1) villous, papillary or fungating (2) gelatinous and (3) diffuse flat, infiltrating types. Structurally or microscopically he divides them into (1) adenocarcinoma (2) alveolar carcinoma and (3) squamous cell carcinoma. The adenocarcinoma which is the most frequent form may produce papillary, gelatinous or scirrhous tumors. The characteristic feature is the production of glandular structures with high columnar cells exhibiting mucus

and the other features typical of carcinoma. Associated with this type of cellular growth will be found pseudoglandular structures with cuboidal cells. A variable amount of connective tissue is present. There is usually a profuse distribution of lymphocytes, especially because of the presence of chronic infection within the wall of the gallbladder. The alveolar type is made up of pseudoglandular or columnar structures; the cells of which may be more cuboidal. Squamous cell carcinoma is the least frequent (10 to 18 per cent) and is composed of cells which may be flattened and attain squamous characteristics because of metaplasia presumably caused by extended irritation created by the gallstones. Practically all malignant tumors of the gallbladder invade the wall rapidly and extend either into the liver or along the lymph nodes of the hilus early in the disease.

Frequently the tumor arises in the proximal portion of the gallbladder or cystic duct. In such instances growth is apt to take place into the lumen of the gallbladder or downward into or along the common duct. At operation it may be impossible to discover at what point the tumor arises unless the tumor is of recent origin.

Clinical Manifestations.—Unfortunately symptoms of carcinoma of the gallbladder rarely manifest themselves until the late stages of the disease. Since cholelithiasis is such a constant accompaniment and precursor of carcinoma there will usually be symptoms of gallbladder disease such as dyspepsia, epigastric discomfort and pain in the right upper part of the abdomen of many years duration. From the history one can rarely tell when the carcinoma itself developed except that pain in the right upper quadrant which will be present in over half the cases will be more constant than it was when produced by cholecystitis or cholelithiasis alone. Nausea and vomiting are fairly common. Loss of weight will be noted in about one third of the cases when the patient is first seen and of course will be universal in the late stages of the disease.

In about half the cases a mass will be palpable in the region of the gallbladder when the patient is first seen. Rarely will the infiltration associated with the tumor be palpated with sufficient accuracy to be of much aid in diagnosis. Metastasis takes place early and extends first to the liver and then to lymph nodes and the surrounding organs. The omentum, duodenum and colon are usually densely adherent to the involved gallbladder even before metastases are extensive.

Jaundice will be present in perhaps one third of the cases; its incidence will naturally

increase with the duration of the disease. Except on rare occasions when severe hepatitis may be present with the tumor the jaundice will be of the obstructive type produced by compression of the intrahepatic bile ducts or the extrahepatic bile ducts (i. e. the hepatic or common duct) by the invading tumor. Obviously the stools are more likely to be pale and acholic if the obstruction is caused by infiltration or glandular metastases along the hepatic duct than if the jaundice is caused by metastasis to the liver alone. The fact that jaundice produced by carcinoma of the gallbladder is persistent and progressive should differentiate it quite readily from the intermittent type of jaundice usually associated with stones in the common duct. The type of jaundice would however be of no value in differentiating the disease from carcinoma of the pancreas and primary carcinoma of the liver.

The differential diagnosis may be so difficult that it cannot be made without performing a laparotomy. Furthermore metastases occur so early that operative removal of the tumor is usually impossible at least by the time clinical manifestations point to the correct diagnosis. However the condition is confused with stones in the common duct so frequently that the surgeon is usually forced to operate lest he be guilty of failing to give the patient the advantages to be derived from a laparotomy when stones are producing the jaundice.

Treatment.—As previously intimated the onset of the disease is so insidious and the appearance of metastases so rapid that by the time the patient comes to operation the condition is hopeless so far as operability is concerned. Occasionally however a gallbladder is removed for chronic cholecystitis and after removal it is discovered that a very early carcinoma is present. In such a case it would appear that a favorable prognosis could be given the patient but this is not true. Occasionally a carcinomatous gallbladder can be removed satisfactorily only by removing a wedge-shaped piece of liver with the gallbladder. It is possible that utilization of this principle might increase the probability of cure. Roentgen therapy may be instituted but very few of the carcinomas of the gallbladder are sensitive to radiation.

BENIGN TUMORS OF THE BILE DUCTS

These tumors are classified either as papillomas or as adenomas. Because of an apparent confusion in the literature it is difficult to determine which is the more common but tumors of the adenomatous type appear to be more frequently reported. Each of them is quite rare however. The adenomas as well as papillomas are usually single but may be multiple and may arise in the gallbladder (Henry). The tumor is usually small but occasionally becomes large and undergoes transition with degeneration into a cystic or myxomatous tumor. The symptoms produced by such tumors are atypical and a diagnosis is difficult to make preoperatively. When the tumor becomes large enough to obstruct the duct it is of course accompanied by jaundice and other obstructive signs depending on its location.

MALIGNANT TUMORS OF THE BILE DUCTS

Invasion of the bile ducts by malignant tumors is more common than invasion by benign tumors and occurs in the intrahepatic as well as extrahepatic ducts. When occurring in the intrahepatic ducts they are classified as primary tumors of the liver but comprise only a small part of these tumors. Almost all malignant tumors of the bile ducts are carcinomas usually of the adenomatous type with cylindrical cells and occur more often in men than women (ratio of 4 to 3) in contrast to the greater frequency of carcinoma of the gallbladder in women. Stones are less common than in carcinoma of the gallbladder. In a study of 464 cases of carcinomas of the biliary tract encountered at the operating table Gray and Sharpe found 291 located in the gallbladder, 119 in the bile ducts and 54 in the ampulla of Vater.

In a series of 81 cases studied by Rolleston and McNece 28 occurred at the junction of the cystic and common duct, 23 at the lower end of the common duct, 19 in the common hepatic duct and 11 in the middle part of the common duct. They are usually small and nodular but occasionally infiltrate the entire duct and form a tubular stricture. The growths are associated with so much fibrous tissue that the malignant nature of the tumor may be overlooked even in

the microscopic sections. Metastases occur slowly. Cholemia associated with the obstruction is one of the major factors in the fatal outcome.

Carcinoma occurring at the ampulla of Vater may not be a true tumor of the bile duct. After the tumor has attained a certain size it is difficult to tell whether it has arisen from the ampulla, the common duct or the duct of Wirsung except that microscopically the tumors which arise in the latter sites are made up of columnar and pheroidal cells respectively. Carcinoma of the ampulla of Vater is particularly slow to invade and is therefore very amenable to treatment (i. e. excision) although the operation itself is quite formidable.

The clinical manifestations of carcinoma of the bile ducts are so inconsistent that an accurate preoperative diagnosis is rarely made. Usually the first symptom is the insidious development of jaundice associated with dyspepsia and perhaps a slight amount of upper abdominal pain. If the obstruction is complete the urine contains bile and the stools are acholic. The jaundice is usually constant and rarely diminishes after being present for a few weeks. Malaise and loss of weight are prominent. The symptoms in fact resemble closely those associated with carcinoma of the pancreas. The condition may be confused with stones in the common duct but the latter disease is usually associated with more severe pain and fluctuation in the depth of jaundice.

When the tumor is located at the ampulla of Vater the symptoms will not be different from those just described. Liver function tests may be helpful in the differentiation of obstructive jaundice of this type from intrahepatic jaundice since the tests are apt to be negative in the former group and positive in the latter i. e. intrahepatic jaundice.

The treatment of tumors of the bile ducts is of course surgical if any hopes are entertained as to permanent relief. Occasionally it will be possible to resect the tumor and to effect an end to end anastomosis with the two ends of the duct perhaps over a vital hum tube. More frequently the tumor will be located at the ampulla of Vater. If it is confined to the region of the ampulla resection as popularized by Whipple will be

indicated. Numerous technics have been devised. The resection may be performed in two stages although there is a tendency in recent years to utilize a one stage procedure particularly if a lot of blood is available for transfusions, the method suggested by Trimble and associates consisting of resection of the duodenum and head of the pancreas with anterior gastrojejunostomy and implantation of the terminal end of the common duct into the distal jejunal loop appears very practical. The various methods have been discussed in detail in the splendid monograph by Brunschwig. Palliative procedures such as the anastomosis of the gallbladder to the duodenum or the stomach may be resorted to when resection is not feasible.

STRICTURE OF THE BILE DUCTS

Etiology.—The causes of stricture of the common and hepatic bile ducts in order of frequency, are operative injury, adenocarcinoma, diffuse inflammation of the biliary tract and in a few instances benign tumor of the biliary tract such as fibroadenoma or neurofibroma.¹

General Considerations.—The report of a case of stricture of the common bile duct by W. J. Mayo²

in 1903 in which an accurate anastomosis was made between the stump of the duct above the stricture and an opening made in the duodenum laid the foundation for the development of plastic surgery of the common bile duct for the relief of stricture. This contribution became notable because of the excellent results that followed proper execution of the method over a period of a quarter of a century.

That most of such strictures are caused by injuries to the bile ducts needs no further proof. In a series of 99 cases reported by Walters and Lewis³ cholecystectomy had preceded the formation of stricture 77 times, cholecystectomy and choledochostomy 13 times, cholecystostomy 6 times and cholecystogastrostomy with choledochostomy once. In 1 case operative procedure had not preceded the discovery of a stricture. Reports that extensive contractures of the ducts have occurred as a result of infection either in the biliary passages or in adjacent structures in cases in which operation had not been performed previously can be found in the medical literature. The possibility that a spontaneous biliary stricture may be carcinomatous is illustrated by Flings' case reported by Riggs in which three months after excision of a stricture at the lower end of the common bile duct and choledochoduodenostomy jaundice again appeared. A mass in the region of this biliary stoma proved to be carcinomatous. Re-examination of a specimen of the stricture that was removed previously after painstaking and careful search revealed the presence of malignant cells. Rolleston was of the opinion that in Andral's case of inflammatory stricture of the common bile duct which was reported in 1831 the lesion probably was carcinomatous. A perforated duodenal ulcer strangling the duct with the products of inflammation was reported in 1876 by Morgan who also stated that in 1860 Holmes had presented before a pathologic society in London a case in which a stricture was supposed to have been caused by the passage of a stone from the common bile duct. If such did occur the possibility that the stone, fretting away at the walls of the duct produced ulceration seems more likely to have been the cause than passage of the stone. Brinkow⁴ reported a case of stricture of the intestinal portion of the common bile duct that he thought might have been syphilitic and he substantiated his belief by demonstrating extensive small round cell infiltration surrounding the bile ducts. Two cases of fibroadenoma in the stump of the cystic duct, in which the typical symptoms of obstruction of the common duct were produced were reported by W. J. Mayo² in 1916. A somewhat similar type of case (neuroma) was reported on by Comfort and Walters⁵ in 1931. Although subsequent to operation there were present in this case some slight evidences of biliary obstruction when the patient was reexamined in 1933 she had been free from symptoms of obstruction for two and a half years. A report from her in 1939 indicated that since her last examination she had experienced some attacks of recurring biliary obstruction.

Prior to 1914 strictures of the common and the hepatic bile ducts were reported for the most part as single cases. In 1911 Jacobson⁶ reported 1 case of his own and reviewed 31 others reported in the literature. He directed attention to the various methods used in

the repair of the strictures as well as to the immediate postoperative results Ellsworth Flot Jr.⁸ in 1918, reported 3 cases of stricture of the hepatic and common bile ducts in which he performed surgical operations. He also made an exhaustive review of the literature and grouped the cases according to the methods of treating the stricture. The results were recorded in each case. In 1930 he⁹ summarized the results of various types of operations performed by many surgeons in the United States and abroad.

McArthur¹⁰ in 1923 and Douglas¹¹ in 1926 reported several of their own cases. Judd and Burden¹² in 1925 reported the results of operation in 18 cases of stricture of the common and hepatic ducts in which operation had been performed and in 1931 Walters¹³ presented the data on the results obtained from various operative procedures for stricture which he had carried out in 30 cases at the Mayo Clinic during the period from 1924 to 1931 inclusive. By 1936 the number of cases had increased to 51 (reported by Nygaard, Stellan and Walters¹⁴) and in 1938 Walters and Lewis¹⁵ reported an increase in the number of cases to 73. The mortality rate in these last 22 cases was 0 per cent. In 1940 Walters and Lewis¹ reported that Walters had operated for stricture of the bile ducts in a total of 98 cases with a mortality rate of 10 per cent. The introduction and use of vitamin K (Butt and others¹⁶ 1935) and bile salts in the preparation and postoperative treatment in such cases which has reduced postoperative bleeding to a minimum has been largely responsible for this reduction in the mortality rate.

Burden¹⁷ and Counsellor and McInloe¹⁸ have made interesting contributions to the knowledge of the stricture size and condition of the biliary tract in health and in disease. In a study of the pathologic anatomy of the bile ducts their summary includes the following statement:

"The most frequent pathologic changes in the ducts are those of inflammation. Cholecystitis nearly always is accompanied by infection in the walls of the ducts. The lesions are those of the usual chronic inflammatory type characterized by lymphocyte infiltration and the production of fibrous tissue. The glands may retain their form and all in its dissemination through the duct. The glands respond to the irritation by an overproduction of mucus and become dilated and cystic. The process of repair is attended by the formation of fibrous tissue which results in a thick and inelastic tube."

Judd and Counsellor¹⁹ called attention to the fact that general obliterative cholangitis may exist months before signs of stricture appear. They noted that strictures of the common bile duct differed from those following simple aseptic ligation in that the infective process was already present in the ducts prior to the operation at which injury was inflicted. The retained bile is rapidly infected and exacerbation of acute cholangitis follows. Although moderate dilatation usually occurs it is rarely extensive and may be entirely absent.

Operation on the Extrahepatic Biliary Tract—This condition is characterized usually by prolonged drainage of bile from the incision which may continue for a period of weeks or months. When the drainage of bile finally ceases jaundice occurs. As a rule this is followed by pain which is usually intermittent and colicky and which may be accompanied by chills and fever and by increasing jaundice. If stricture is complete the biliary fistula may recur, pain and fever subsiding with the discharge of bile. If stricture is incomplete the symptoms of biliary obstruction subside with discharge of bile past the region of stricture into the duodenum. Jaundice in either type of stricture varies according to the degree of obstruction in most cases tending to be constantly present in varying degrees. The serum bilirubin value (van den Bergh) varies similarly. The general systemic effects of both incomplete and complete stricture are due principally to the effects of biliary obstruction and cholemia and associated intrahepatic infection and are characterized in addition to the symptoms mentioned by loss of weight and secondary anemia. Pruritus is usually present.

2. Carcinomatous Obstruction of the Common and Hepatic Ducts—Malignant obstructions of the common bile duct occur with comparative infrequency. Judd, McIndoe and Marshall²⁰ cited Kelzwick as observing but 2 instances in 4,578 routine post-mortem examinations and McGinn found 5 in 9,000. Of 22,000 operations on the biliary tract at the Mayo Clinic, 41 were performed for carcinoma of the bile ducts. Such malignant lesions occur infrequently and produce a high mortality rate. The results of any type of operative procedure on the biliary tract in which such malignant strictures are present are poor.

The lesion occurs more commonly among males than among females and in about 50 per cent of the cases there are associated stones in the gallbladder or in the bile ducts. Although the tumor may be found to involve any portion of the common or hepatic bile ducts it most frequently occurs either at the junction of the cystic and common ducts or at the division of the hepatic duct into its main branches. Rarely is the lesion localized sufficiently to be excised. One pa-

Symptomatology and Pathology.—

1. Stricture of the Common Duct Follow-

tient who was operated on for such a lesion by W. J. Mayo in 1904 was living and well in 1917.

The clinical picture produced by carcinoma is not different from that produced by any other type of obstructing lesions of the common bile duct although when obstruction occurs the jaundice is likely to be painless more frequently than otherwise. Biliary obstruction which occurs as a result of a malignant lesion of the common or the hepatic bile duct is characterized by the development of progressively increasing jaundice. At first when the lesion is small the obstruction may be incomplete producing attacks of intermittent pain associated with fever. In this stage of the obstruction it is impossible in most cases to distinguish the condition from that which results from a benign obstructive lesion that is mainly stone in the common duct. When biliary obstruction becomes complete as a result of malignant obstruction of the common and hepatic ducts as in biliary obstruction due to carcinoma of the head of the pancreas the level of serum bilirubin in the blood reaches a much higher level than in cases of benign obstruction and occasionally reaches a concentration of 25 mg. or more per hundred cubic centimeters.

The general condition of the patient as regards weight, anemia and pruritus closely parallels that of any other patient who has a similar degree of jaundice regardless of the type of biliary obstruction.

3. *Stricture Due to Diffuse Inflammation of the Biliary Tract*—This condition occurs with extreme rarity. With but 1 exception patients suffering from benign stricture of the common bile duct on whom Walters has operated have presented histories of having previously undergone operative procedures on the biliary tract. The symptoms in cases of this type usually appear insidiously with evidences of degree of the biliary tract and minor degrees of biliary obstruction. Disposition is similar to that of cholelithic disease occurs and is followed later by biliary colic associated with jaundice. The attacks of pain and the depth of jaundice increase as the inflammatory lesion progresses to cause more nearly complete obstruction. In the early stages of obstruction of this type bile can be obtained on duodenal drainage

which decreases progressively as the obstruction becomes more nearly complete.

4. *Stricture Due to Benign Tumor of the Biliary Tract*—This condition manifests symptoms similar to those of stone in the common duct obstructive symptoms depending on the degree of obstruction caused by the tumor.

Differential Diagnosis.—Symptoms from lesions of the common and hepatic ducts are dependent on the degree of biliary obstruction and the presence or absence of cholangitis regardless of the pathologic character of the lesion. For this reason it is difficult in most cases to distinguish between benign and malignant strictures of the ducts. It is similarly difficult preoperatively to distinguish between biliary obstructions due to stricture and those due to stone when the patient has undergone a previous operation on the biliary tract. When there has not been a previous operation stone is the more likely cause especially since spontaneous inflammatory strictures of the ducts are rare. One important exception is noteworthy and that is the frequency with which abnormally prolonged drainage of bile from the incision subsequent to operation on the biliary tract is evidence of injury to the duct which sooner or later is followed by stricture.

If a patient presents himself with an external biliary fistula having been operated on elsewhere before transplantation of the fistula is considered the condition of the common and hepatic bile ducts and of the gallbladder should it remain must be ascertained. For example if material resembling the white of egg is excreted the probabilities are that the gallbladder remains and that there is a stone in the cystic duct. When bile is excreted the probabilities are that the obstruction is in the common bile duct and that it is caused by stone by stricture or by a tumor in the head of the pancreas. In most cases the outline of the ducts can be obtained by roentgenographic examination of the region after the injection of radiopaque substances (lipiodol and brominol) through the sinus into the ducts. In some cases however visualization may not be satisfactory and it will be necessary to determine the length of the common or hepatic duct remaining above the stricture at the time of reoperation.

Medical Treatment.—Medical treatment consists largely of relief of pain and preparation of the patient for operation. When an external biliary fistula is present, an effort should be made to return the bile to the digestive tract by mixing some of it with such cholelithic liquids as grape juice. One patient who had an external biliary fistula from carcinoma of the ampulla took bile mixed with grape juice daily for more than a year. In some cases bile has been diluted and given by proctoclysis, in general however it is irritating and uncomfortable to the patient and especially so when administered by proctoclysis. The control of pruritus is a difficult matter. The proper application of lotions and the administration of procaine hypodermically are of some aid. Intravenous injections of small dilute quantities of procaine will at times give a brief respite from severe intractable pruritus.²¹

but even so the incidence of serious postoperative hemorrhage in such cases is rare. Three thousand cubic centimeters of fluids are given orally, intravenously or by proctoclysis daily. Infusions of 1000 to 2000 cc of 10 per cent glucose in physiologic salt solution also are administered and a high carbohydrate diet is employed. In cases of profusely draining fistulas the concentrations of the blood urea and of electrolytes should be determined and any imbalance should be restored to as nearly normal level as possible. If a patient is deeply jaundiced and there is difficulty in controlling the hemorrhagic tendencies with vitamin K, a preoperative transfusion of 500 cc of freshly drawn blood is given. It has been shown that the prothrombin content of stored blood fall rapidly.

(b) *Operative procedures for benign strictures can be divided into five groups:* (1) hepaticoduodenostomy

Fig 609—Choledochoduodenostomy with end to side anastomosis

Surgical Treatment.—(a) *Preoperative treatment* consists of the administration of abundant fluids vitamins especially thiamine chloride and vitamin K (orally and parenterally) the intravenous injection of glucose and in an occasional case transfusions of blood in an attempt to improve hepatic function and to decrease the prolonged coagulation time of the blood caused by the disturbances of hepatic function and the deficiency of prothrombin.²² Clinical data indicate that certain naphthoquinones which have been designated as synthetic vitamin K increase the prothrombin content of the blood in cases of jaundice and decrease the hemorrhagic tendencies of jaundiced patients. The use of synthetic vitamin K substances (naphthoquinones) has permitted rapid increase in the prothrombin content of the blood when these compounds have been administered intravenously. In some cases when extensive hepatic damage is present administration of vitamin K in any form will not have as beneficial effect on the prothrombin as in other cases,

choledochoduodenostomy (Fig 609) and cholecystoduodenostomy (Fig 610), (2) excision of the strictures or tumor with anastomosis of the ends of the duct (3) plastic operation for localized stricture which consists of longitudinal incision of the stricture followed by transverse closure after the method of a Heineke Mikulicz pyloroplasty (4) transplantation of an external biliary fistula established when a sufficient amount of common or hepatic duct does not remain to permit anastomosis of the duct and the duodenum and (5) resection of the ampulla of Vater for carcinoma.

The following general considerations will guide in the selection of the surgical procedure.

1. The permanent implantation of a vitallium tube in the treatment of injury or stricture of the bile ducts as advocated by Pearse,²³ constitutes an important contribution to this type of surgery. Pearse advises using a straight 3.3 cm by 6 mm tube with a central flange to anchor it in place in order to hold open a

structured area of the common bile duct. For a stricture of the common hepatic duct within 1 cm. of the bifurcation of the hepatic ducts he advises using trumpet-shaped Y or half Y tubes.

Fig. 610—Cholecystoduodenostomy for stricture of the lower end of the common duct

entation of the hepatic ducts he advises using trumpet-shaped Y or half Y tubes.

the liver is in satisfactory condition. In 31 of the 98 cases of stricture of the common duct (reported by Walters and Lewis³) in which Walters operated cholecystoduodenostomy was performed. Twenty-eight patients were well at the time the reported study was made. In the group of 31 cases there was only 1 post-operative death. 5 patients died after dismissal and 2 patients experienced recurring obstruction. Hepaticoduodenostomy was performed 31 times. In this group of cases only 13 patients were well at the time the study was made. Two patients died postoperatively and 8 died after dismissal. Eight patients had recurring symptoms. In 4 of the series of 98 cases stumps of both the right and the left hepatic duct were discovered above the structured common hepatic duct and 1 common bile duct. The stumps were anastomosed separately to the duodenum over rubber tubes of the Mayo-Sullivan type (Fig. 611).

Failure to obtain a good result with any of these methods can be attributed directly to inaccurate anastomosis to severe infection of the parenchyma of the liver or to infection in the walls of the biliary tract itself. Infection in either of the structures mentioned may be accompanied by sand-like calculi within the biliary passages.

3. If the stricture or tumor is small or if it is situated directly adjacent to the liver with normal duct both proximal and distal to it, excision of the lesion with subsequent direct anastomosis of the ends of the duct probably will be a satisfactory procedure and can be expected to be followed in many cases by good results. Such is not usually the case, however, if the scarred portion is merely incised and allowed to remain, even though the lumen of the duct at this point

Fig. 611—Method of separate anastomosis of the right and left hepatic ducts to the duodenum

* If sufficient normal duct remains above the stricture to permit its accurate anastomosis without tension to an opening made in the duodenum, thus obtaining union of mucous membrane to mucous membrane (Fig. 609) results will be excellent, provided

is increased by a plastic procedure of the Heineke-Mikulicz type. This failure may be explained by the fact that the remaining scar tissue continues to contract. In 11 of the 98 cases in which Walters operated he performed some form of plastic operation on the

bile ducts One patient died within a short time post operatively and 2 died subsequently of the 11 patients who underwent plastic procedures 6 were well and 2 had had recurring attacks of jaundice

denum This procedure may be expected to be followed by good results in some instances and by fairly good results in others This operation however is the least satisfactory of the methods outlined and recur

Fig 612—Establishment of an internal biliary fistula in a case of complete stricture of the extrahepatic ducts

Fig 613—Exploration of the hilum of the liver with an aspirating needle which then is used as a guide for the scalpel A catheter is inserted into the duct for drainage

4 If the amount of duct that remains exterior to the liver is not sufficient to allow for either procedure, an external biliary fistula can be established and later coned out and transplanted into the stomach or duo-

denum In the group of cases in which it is used are high This method was employed in 9 cases with satisfactory results in only 2 although there was only 1 death during the postoperative period

A more satisfactory type of operation is the immediate suture of no opening in the duodenum about the hilum of the liver. This procedure is carried out after a dilated duct is discovered in the hilar region of the liver. A short catheter is inserted into an opening made in the duct and a small opening in the duodenum in the shape of a fish mouth then is sutured about the catheter to the hilum of the liver.

In December 1933 Walters operated on a woman aged twenty-six years for complete stricture of the extrahepatic ducts using a procedure such as that described in the preceding paragraph (Fig 612). The patient received considerable relief although occasional attacks of subacute incomplete biliary obstruction occurred subsequently.

If transplantation of an external biliary fistula is deemed the procedure of choice it must adequately

Fig 614—Spontaneous communication of an external biliary fistula with the duodenum caused by pressure necrosis of an indwelling catheter.

drain the intrahepatic ducts and these ducts must be free of stones otherwise the obstruction will recur. Furthermore the possibility of a more certainly curative type of operative procedure namely hepaticoduodenostomy should be considered if sufficient normal duct remains above the stricture or the fistula to enable the duct and the duodenum to be accurately anastomosed.²⁴

In 18 of the 99 cases reported by Walters and Lewis extrahepatic ducts could not be found. In such cases the following technique permits discovery of a dilated intrahepatic duct. An aspirating needle is introduced into the region of the hilum of the liver until bile is obtained. A small scalpel on a long handle then is introduced alongside the needle which is left in place to act as a guide (Fig 613). The opening into the duct is enlarged to permit the introduction of a good-sized catheter (20 to 26 F). In 17 of the 18

cases this method or a modified procedure permitted the establishment of an external biliary fistula. In 2 cases in which external biliary fistulas were formed the pressure necrosis of an indwelling catheter produced a spontaneous communication between the fistula and the duodenum. In 1 of these cases the spontaneous communication (Fig 614) developed about nine months after the operation and two years later this patient was enjoying good health.

The frequency with which small tumors of the ampulla of Vater cause obstructive jaundice should not be forgotten. Since the tumor is usually small and is of a low degree of malignancy, producing symptoms early and metastasis late it lends itself readily to transduodenal removal. Rarely the tumors are benign.

In a consideration of the various methods of operation for tumor of the ampulla of Vater, it is only fair to give credit to palliative or conservative methods of relieving obstruction by anastomosis between the biliary and intestinal tracts and to call attention to Abell's²⁵ interesting case in which radium was applied to an ingenious method to the ampullar lesion. If the patient is deeply jaundiced or if his condition is such that resection of the ampulla cannot be accomplished with a reasonable margin of safety it would seem that the palliative operation of biliary intestinal anastomosis is indicated.⁴ On the other hand if the patient is in good condition and the lesion is producing such symptoms as bleeding which may terminate the patient's life unless it is stopped it would seem that resection should be undertaken. In support of the argument favoring ampullar resection in indicated cases is the relatively low malignancy of carcinomas of the ampulla of Vater. Hunt and Budd²⁷ in a review of 63 cases reported in the literature found that the risk of radical extirpation was 38 per cent of 47 survivors of radical operation 10 had died of recurrence within one year. Cholecystostomy or more desirably cholecystogastrostomy is advisable preliminary to resection of the ampullar lesion if the patient is deeply jaundiced.

It is an interesting fact that the operative mortality rate among patients who have malignant lesions of the extrahepatic biliary passages is exceedingly high regardless of the type of surgical procedure carried out. This is true even when such a minor procedure as removing a specimen of the lesion for microscopic examination is done. Indeed it is likely to be the case also if an exploratory operation alone is carried out without excision of any tissue. The reason for this high mortality probably lies in the fact that as a result of the prolonged jaundice a considerable degree of hepatic impairment is present. In addition the effect of the malignant disease probably tends to lower the general vitality and resistance of the patient. The increasing knowledge of hepatic disease and the treatment of various deficiencies with vitamins and glucose have greatly reduced the mortality. In cases in which patients failed to recover from operation postmortem examination reveals as a rule various degrees of cholangitis and hepatitis, hepatic abscesses and destruction of hepatic cells. The use of vitamin K has diminished greatly the occurrence of hemorrhage even when considerable hepatic damage exists.

In cases of benign stricture of the common bile duct the operative risk is not nearly so great although in

any large series of cases the operative mortality rate will vary from 10 to 20 per cent. In the series of 98 cases in which Walters operated, the operative mortality rate was 10 per cent. The surgical procedures included operations on 18 patients who had complete stricture of the extrahepatic ducts. Only 1 postoperative death, however, occurred in 31 cases in which choledochoduodenostomy was performed, a mortality rate of 3 per cent. Provided it is possible to relieve the biliary obstruction completely, the risk of the operation will depend for the most part on the ability of the liver to regain its function. Relief of obstruction is the essential purpose of any operative procedure on the jaundiced patient, for unless the obstruction is completely relieved, hemorrhage or infection usually will terminate the picture, and the control of such hemorrhage, even though vitamin K is administered is directly dependent on the ability of the liver to function. Persisting postoperative infection and cholangitis frequently respond to administration of sulfanilamide and other chemotherapeutic agents. The judicious use of choleric agents such as decholin (dihydrocholic acid) may aid in "flushing" the biliary passages and relieving stasis and associated infection.

Summary.—From 1924 to 1940 Walters operated on 98 patients who had benign strictures of the common bile duct; this number included 18 patients who had complete stricture of the extrahepatic ducts. Ten patients died in the hospital subsequent to operation, a mortality rate of approximately 10 per cent. In 4 cases (before the introduction of vitamin K) the immediate cause of death was postoperative hemorrhage. A study made in 1940 revealed that of the 98 patients, 52 (53 per cent) were living and well. Of the 34 patients, however, on whom choledochoduodenostomy had been performed, 28 (82 per cent) were living and well.

In the entire series of cases, choledochoduodenostomy was performed 34 times and hepaticoduodenostomy 31 times; plastic reconstruction of the bile duct was possible 11 times. This group yielded by far the most favorable results, in that there were only 4 deaths, a mortality rate of 5 per cent. Sixty-two per cent of these patients were well in 1940 at the time the study was made.

The use of sulfanilamide has aided in the control of recurring attacks of cholangitis, and the introduction of vitamin K has reduced greatly the danger of postoperative hemorrhage.

CONGENITAL OBSTRUCTION OF THE BILE DUCTS

Etiology and Pathology—According to Albo and other observers the bile ducts in their process of development pass through a solid stage analogous to that of the intestine. An arrest in development during this solid stage more adequately explains the malformations found than any of the other theories advanced.

The gross pathologic findings associated with these obstructions of the biliary ducts are general icterus enlargement of the liver and a wide variation in the malformation of the ducts.

Symptoms and Diagnosis—The diagnosis is of congenital obstruction of the bile ducts may be quite difficult to make in the first few weeks of life but it becomes simpler as the infant grows older. The jaundice

is present a few days after birth and grows more intense as the infant enters the second month of life. It is of a greenish yellow tinge rather than the marked yellow seen in biliary obstruction of adult life. The stools are acholic as a rule but may at times give a positive test for bile or may show gross evidence of bile on their surface even in cases of atresia or complete absence of extrahepatic ducts. This is explained by the excretion by the intestinal mucosa of the bile carried in the blood stream. The urine contains bile and the icterus index is usually high. The bleeding and clotting time may be slightly prolonged. The fragility of the red blood cells is normal. Slight anemia has been observed in some of the patients. The patients show a surprisingly good state of nutrition and development even when several months old. The striking features are the general icterus and the enlarged liver with a hard edge.

Other diseases may be confused with this condition for instance icterus neonatorum which is not serious and which generally disappears after the second week. While the degree of icterus during the first two weeks of life may be the same as in cases of obstruction the infant with icterus neonatorum does not have an enlarged liver acholic stools or bile in the urine. Erythroblastosis foetalis is likely to have an early fatal outcome but before death the infant usually shows an enlarged spleen and an increased number of erythroblasts in the blood smear. Jaundice of hemolytic sepsis does not show acholic stools bile in the urine a high icterus index or progressive jaundice. Sphingolipid is ruled out by serum tests of patient and parents and by roentgenograms of the bones.

With few exceptions it is better not to operate before the end of the first month. Nothing is lost by this delay and the assurance of a correct diagnosis is gained. It is not wise to put off the operation beyond the second month as these jaundiced infants have a low resistance to infections from which they may die.

Treatment—The treatment is surgical. The type of operation used on the small infants varies with the lesion found. The operation is not easy on account of the small

size of the structures and their variations from normal. In case the common duct is not readily identified, it is helpful to insert a small catheter into the gallbladder and to

was theoretically unenable to relief by surgical methods. Thirteen of the 19 patients with complete obstruction whose condition was operable have recovered. The 6 patients

Fig 615—Atresia of the common duct, showing the technique of end to side anastomosis over a small piece of rubber tube, with a single row of interrupted mattress sutures of fine silk.*

inject saline solution through it. If the cystic duct is patent and the common duct is not, this procedure will distend the common duct and make its isolation easier. When atresia of the common duct is demonstrated, the gallbladder may be anastomosed to the stomach or duodenum. This is a simple procedure but is not the operation of choice except when the patient's condition does not warrant the somewhat more difficult operation of choledochoduodenostomy. The common duct is so small that the ordinary methods of anastomosis are not feasible (Fig 615). Hence, it is performed over a short piece of rubber catheter, and in case of an extremely small duct a very small piece of ureteral catheter is used. For the smallest duct we have successfully anastomosed, a segment of no. 4 ureteral catheter was used. The suture material was very fine silk. The catheter is left in place to be carried on by intestinal peristalsis (see roentgenogram in Fig 616). In one instance a successful anastomosis between the hepatic duct and the duodenum was carried out in the same manner as that described for the common duct.

Prognosis—The mortality for the patients with complete obstruction without operation is, obviously, 100 per cent. In our series of 60 cases there were 54 cases of complete obstruction and 6 of partial obstruction. In 24 of these 60 cases the condition

with partial obstruction all recovered but 2 have had occasional return of symptoms. In this group the late results suggest that

Fig 616—Roentgenogram of the patient with atresia of the common bile duct. Note the rubber tube over which the end to side anastomosis of the common bile duct to the duodenum was made.*

choledochoduodenostomy is preferable to cholecystoduodenostomy or cholecystogastrostomy.

XXXI. THE PANCREAS

SURGICAL DISEASES OF THE PANCREAS

Anatomy.—The pancreas is deeply located in a retroperitoneal position behind the aetosal floor of the *crural bursa* at the level of the first and second lumbar vertebrae. It extends from the duodenum on the right to the spleen on the left. The organ may be divided into a head, neck, body and tail. The head of the organ is rolled into the loop of the duodenum. Posteriorly the head lies on the vena cava and portal tributaries while the body crosses the aorta, renal vessels, suprarenal gland and left kidney. The tail may be intimately related to the spleen. The stomach is anterior, the transverse mesocolon is inferior and at the extreme left will be found the splenic flexure of the colon. The upper margin is grooved or tunneled by the splenic artery.

Tumors of the pancreas may compress the inferior vena cava and portal tributaries and cause ascites. Carcinoma of the head of the pancreas usually compresses the common bile duct and causes jaundice. An ulcer on the posterior wall of the stomach may erode into the pancreas. The tail may be injured during splenectomy or nephrectomy. Solid or cystic growths will project forward through the gastrocolic or the gastrohepatic omentum or posteriorly through the transverse mesocolon. The main pancreatic duct of Wirsung traverses the entire length of the gland and opens into the ampulla of Vater, usually in association with the common bile duct. This is important, because if the opening into the duodenum is obstructed the bile may pass into the pancreatic duct and set up pancreatitis. An accessory duct (Sanctum) is usually present and communicates between the main duct and the duodenum cephalad to the ampulla.

The pancreas is supplied by the splenic and superior and inferior pancreaticoduodenal arteries. The lymphatic distribution is rich and drains mostly into the pancreaticoduodenal and aortic nodes. The nerves are derived from the solar plexus and the vagus.

Physiology.—The pancreas is intimately concerned in the metabolism of carbohydrate, fat and protein. It is concerned with the linking up, storing and preparation of energy for utilization in the tissues.

The external secretion poured into the duodenum is important for digestion by reason of its ferments (trypsin, amylase, lipase, renin, maltase and possibly erepsin). Unlike the gastric enzymes, apparently those of pancreatic juice are produced by one type of cell. Trypsin or pancreatic protease is a much more powerful proteolytic enzyme than pepsin. As secreted by the pancreas, it exists as the proenzyme in an almost inactive state which is converted from trypsinogen to trypsin by the enterokinase of the duodenal secretion. Conversion of trypsinogen to trypsin in the pancreas results in digestion of pancreatic tissue, presumably the mechanism in pancreatitis. Proteins are

hydrolyzed to the dipeptide, tripeptide and tetrapeptide stage by the action of this enzyme. Pancreatic amylase acts in a fashion similar to that of salivary amylase, causing rapid hydrolysis of starch. Pancreatic lipase splits the fat molecules into the constituent fatty acid and glycerol.

The internal secretion derived from the islets of Langerhans has to do with the carbohydrate metabolism, and if it is deficient diabetes results. This secretion, under the name of insulin, may be administered artificially and thus may regulate the diabetetic state if assisted by proper diet.

ANOMALIES OF THE PANCREAS

Abnormalities of the pancreas may be divided into those of the gland and those of its ducts.

An accessory or aberrant pancreas may exist in the walls of the stomach, duodenum, jejunum or ileum; the pancreas may be cleft almost into two parts; it may have outlying lobules or may by enlargement of its head almost completely encircle the duodenum (annular pancreas).

The normal arrangement of the common duct and pancreatic duct uniting to form the ampulla of Vater may be altered so that (1) the pancreatic duct joins the common duct some distance from the duodenum the ampulla being absent; (2) the two ducts open separately into a fossa, the ampulla and entrance being absent; (3) the two ducts open separately at the apex of the entrance, the ampulla being absent; (4) rarely, the common duct unites with the duct of Santorini.

As to the two pancreatic ducts, the rule is that both are present and they anastomose with each other; the duct of Wirsung is the larger. Occasionally the duct of Santorini is separate and may be the larger in 25 per cent of bodies; the duct of Santorini is obliterated near its termination (Opie) and if the duct of Wirsung is occluded in such a case secretion is entirely obstructed.

While a movable pancreas is practically unknown as a clinical entity, it may fall downward or forward or may be part of the contents of a diaphragmatic hernia or very rarely may be contained within the sac of an umbilical hernia.

TRAUMATIC PANCREATITIS

Etiology.—Injury of the pancreas uncomplicated by severe trauma to other organs, is a rare occurrence. Forty six cases only, of subcutaneous injury, have been collected by Stuart (1921). In a study of 965 cases of gunshot wound of the abdomen Wallace (1917) found that the pancreas was wounded five times. The pancreas is injured by a sudden, severe force that drives the or-

gan against the vertebral column and crushes it. The patient may be caught between ears, may be run over, may be kicked by a horse or may fall against the edge of a

tion. Shock or collapse occurs, and there is intense pain in the epigastrium. Rigidity is present. Nausea and vomiting occur. There may be dullness in the flanks, owing to the

table. A bullet wound of the abdomen may involve the pancreas, along with other neighboring organs. Such an injury gives rise to severe shock and hemorrhage.

collection of blood. If the contusion or laceration is slight in extent, the patient may suffer few symptoms, but later a cystic swelling develops in the epigastric or left

Fig 618—Sagittal section to show surgical approaches to the body of the pancreas. *A* is the approach through the gastrohepatic ligament, *B* is the approach through the gastrocolic ligament, *C* is the transmesocolic approach †

Symptoms.—There are no cardinal symptoms. Complicating injuries to other organs usually produce the recognizable symptoms, and the pancreatic lesion is found at opera-

tion. Shock or collapse occurs, and there is intense pain in the epigastrium. Rigidity is present. Nausea and vomiting occur. There may be dullness in the flanks, owing to the

creatic fluid into the lesser peritoneal cavity and is to all intents and purposes a pseudo pancreatic cyst.

Treatment—If the diagnosis is made or suspected if the symptoms are severe and if the condition of the patient permits the abdomen should be opened the lesser cavity exposed and the rupture tamponed or sutured. The latter is to be preferred but as a fistula almost always results drainage must be provided. If the patient recovers the fistula persists and usually closes spontaneously in five or six weeks. The exclusion of carbohydrates from the diet is often recommended but is of no material benefit. If the fistula persists indefinitely it may be necessary to reoperate and remove the distal portion of the gland.

WOUNDS OF THE PANCREAS

Gunshot and stab wounds may occasionally involve the pancreas alone but usually affect other organs as well. The probable course of the bullet and the locations of the wounds of entrance and exit are usually the only guides. Prompt operative intervention should be undertaken and the wound treated by suture or tampon. Drainage is always indicated.

The pancreas is occasionally injured during the performance of operations on other organs. In the operation of partial gastrectomy an adherent ulcer may necessitate shaving a part of the pancreas. No harm seems to result. Injury to the tail of the pancreas has accompanied splenectomy and unless the gland is well ligated it may result in a fatality. More serious is the injury done during the performance of nephrectomy when the clamps have grasped the pancreas. Young (1917) thinks that this accident should be suspected when the operation is followed by rapid prostration and extreme distention.

PARENCHYMATOUS INFLAMMATIONS

The parenchyma of the pancreas may be attacked by a necrotizing inflammation hemorrhagic in character and either acute or subacute in its manifestations by a suppurative infection due to microorganisms or by a chronic interstitial sclerosing process involving the interlobular or intercapillary portions of the gland.

ACUTE HEMORRHAGIC PANCREATITIS

Etiology—Polka (1906) and Gulek (1904) feel that the exact mechanism concerned in the production of the acute hemorrhagic lesion is due to a sudden activation of the trypsinogen by the retrojected bile in cases of obstruction at the papilla of Vater causing autodigestion of the gland. Drigstedt (1934) feels that the lesion is not produced by autodigestion but that the necrosis of the gland results from direct action of the bile salt present in the bile resulting in a fertile medium for the growth of organisms resident in these tissues particularly anaerobes which by their rapid growth give rise to the toxic symptoms. Rich and Duff (1936) feel that the commonest cause of acute pancreatitis is due to obstruction to the flow of pancreatic juice resulting from metaplasia of the epithelial lining of a branch of the pancreatic duct within the gland itself. The ductules and acini behind the obstruction become dilated rupture and permit escape of pancreatic juice into the glandular substance. The interstitial tissue of a pancreas in common with the tissues of the remainder of the body possesses the power to activate the trypsinogen within the gland resulting in autodigestion. These observers have found metaplasia of the duct epithelium and acinar dilatation in 13 of 24 cases of hemorrhagic pancreatitis. In the great majority of these cases no obstruction to the main duct was found nor was there any occlusion at the papilla of Vater. It is also pointed out by these workers that rupture of the duct is most likely to occur when the intraductal pressure is greatest particularly after a meal.

A commonly discussed etiological factor is infection spreading from the biliary tract and especially the gallbladder by way of the lymphatics. There is no good evidence for believing that infective lymphangitis can spread to the region of the head of the pancreas block the exit paths from the pancreas and produce lymph stasis in the head of the pancreas with consequent pancreatitis. There is no anatomical evidence that the lymphatics of the biliary tract area do more than communicate with the pancreatic area outside the capsule of the pancreas.

The disease occurs more frequently in men than women and between the ages of

twenty and fifty. These persons are said to be more often affected. Usually the patient gives a history of repeated mild attacks previously or has disease of the gallbladder. Acute interstitial pancreatitis without necrosis or abscess is fairly frequently observed concomitantly with acute cholecystitis especially with empyema of the gall bladder and is no doubt the forerunner of chronic pancreatitis.

Acute hemorrhagic pancreatitis is more of a necrosis than an infection and the chocolate like fluid in the lesser cavity is usually sterile in early typical cases. The disease results from the action of liberated ferments on the surrounding tissue.

Symptoms—The clinical picture was described by Fitz in 1889 in these words: "Acute pancreatitis is to be suspected when a previously healthy person or sufferer from occasional attacks of indigestion is suddenly seized with violent pain in the epigastrium followed by vomiting and collapse and in the course of twenty four hours by a circumscribed epigastric swelling tympanitic or resistant with a slight rise of temperature."

The patient may have been previously in good health or may have been a sufferer for years from attacks of so called indigestion or of gallstones. Acute violent pain is the symptom of onset. It is referred to the epigastrium and is followed by nausea and vomiting. Early collapse with its attendant symptoms is usually observed and is caused by the intense pain and the rapid involvement of a great part of a vital organ. The abdominal muscles become extremely rigid and in the course of twenty four hours the epigastrium becomes tender, swollen and tympanitic. The pulse rate steadily rises, the temperature also rises if reaction from shock takes place from secondary changes in the gland. Cyanosis has occasionally been observed. Jaundice may be present and is accompanied by constipation and clay colored stools.

Death may occur within twenty four hours but if the patient survives the acute stage the pancreas gradually becomes gangrenous. The symptoms subside at first but the pain persists. The epigastrium remains distended and vomiting recurs at intervals. Belching and hiccoughing are frequent symptoms. High fever, chills, leukocytosis

and rarely fatty stools and glycosuria appear in the later stages and a tumor mass may be demonstrated in the epigastrium and extending to the left.

Diagnosis—Acute pancreatitis is usually confused with intestinal obstruction owing to the acute onset, the cramp like pains, the distention and vomiting. But the intense shock and the localization of the symptoms in the epigastrium are of great importance in diagnosing pancreatitis. Jaundice, absence of fecal vomiting and the slight distention localized in the upper abdomen are also suggestive of pancreatitis. If the patient survives the first thirty six hours the diagnosis should not be in doubt as in intestinal obstruction there will be persistent fecal vomiting, increasing distention, constipation and signs of peritonitis.

In appendicitis the pain and tenderness may at first be felt in the epigastrium but in a few hours they become localized in the right lower abdomen. In acute cholecystitis and in biliary colic the pain is located to the right of the median line and radiates to the back and subscapular regions and the tenderness and swollen condition of the gall bladder may also be elicited to the right and beneath the costal margin. In perforating gastric or duodenal ulcer the previous history, the intense rigidity and the rapid recurrence of distention obliterating the liver dullness are important differential points.

Estimation of the urinary diastase and blood amylase levels seems to be of value in the diagnosis of acute pancreatitis. Under normal circumstances from ten to twenty-four diastatic units are excreted in the urine daily and the values for blood amylase as determined by McCorkle and Goldman (1949) rarely exceed 180 units although Comfort (1942) has given 370 units as the upper limit of normal. An index of 900 or more diastatic units in the urine is taken as significant. Values above 180 for the blood amylase are likewise significant. The exact mechanism producing the elevation in both of these substances is unknown. It has been postulated that during acute hemorrhagic pancreatitis edema of the acini and ducts results in rupture and liberation of the pancreatic juices into the interstitial tissue with consequent absorption by the blood stream. Wohlgemuth's technic seems the best for

the determination of the urinary diastase while Samols's method for the determination of amylase is probably the best in this regard.

Recent observation indicates that pancreatic function is likewise impaired to a measurable degree by chronic inflammatory disease. Ligerlof (1939) using the two tube technic showed marked increase in secretion of pancreatic juice upon intravenous injection of secretin. In cases of chronic inflammatory and sclerosing lesions the reaction of secretin is greatly diminished while in obstructive lesions of the papilla of Vater or the head of the pancreas the flow is absent. This may help to differentiate these patients from the jaundiced patient with carcinoma of the common or hepatic ducts. Secretin increases the volume and alkalinity of the juice while methylacetylcholine increases the contents of the ferment without increasing the volume or alkalinity of the juice.

Prognosis—The majority of these patients die no matter what treatment is undertaken. As a general rule however early rapid operation offers fair prospects of cure if the patient is not in extreme shock. In subacute cases an abscess often develops in the lesser cavity or about the left kidney more rarely a subphrenic abscess occurs.

Treatment—Immediate operative treatment should be undertaken if the patient is seen in the first forty eight hours after this time it may be wise to wait until a localized collection is formed.

The incision is made in the median line above the umbilicus and the abdomen opened, the escape of bloody fluid the characteristic areas of fat necrosis and the swollen pancreas will confirm the diagnosis. The lesser cavity is then opened by tearing through the gastrocolic omentum and the pancreas is exposed it should be incised in several directions the fluid in the lesser sac mopped out and free drainage effected by rubber tubes and gauze tampons. If an abscess has formed or there is much necrosis of the surrounding tissues a posterior stab wound in the left loin will drain the sac at its dependent portion.

The gallbladder and bile ducts must then be inspected and stones removed and drainage instituted if stones are present if there is infection of the tract or if jaundice is pres-

ent. A separate incision may be necessary for this performance. As little anesthesia as possible should be given and chilling of the patient avoided. In the after treatment the patient should be placed on an antidiabetic diet to lessen the irritation of the pancreatic secretion.

Mild Forms of Acute Pancreatitis—While the violent form of acute hemorrhagic pancreatitis may be taken as a type surgeons sometimes encounter an acute pancreatitis without hemorrhage. This may be an acute edema of the pancreas or there may be areas of necrosis with little or no hemorrhage. Chronic or subacute cholecystitis is associated with it.

The patient complains of an intense pain in the epigastrium usually radiating to the left. Nausea and vomiting are not outstanding symptoms. There is no shock. Tenderness to deep pressure in the epigastrium will be elicited. Fever, increased pulse rate and leukocytosis are moderate. It is hard to differentiate the condition from gallstone colic and sometimes from a penetrating peptic ulcer unless roentgen examinations are feasible. The absence of pain on deep inspiration with a finger under the right costal margin is helpful.

Treatment—If acute pancreatitis is suspected surgical treatment should be advised because of the possibility that hemorrhagic pancreatitis may supervene or an abscess may develop. The pancreas should be approached through the gastrohepatic omentum and the peritoneum over it incised transversely and widely. The area should be well drained with rubber covered gauze drains. The gallbladder should be removed. The common duct should be drained if jaundice is present or if the icterus index is high. If the pancreas seems large and hard in the head and jaundice is present some surgeons prefer cholecystogastrostomy or cholecystoduodenostomy. Choledochostomy is rarely indicated.

CHRONIC PANCREATITIS

Etiology—Chronic inflammation of the pancreas may represent simply moderate sclerosis with vague digestive disturbances and epigastric pain or a definite tumor mass with jaundice and cachexia simulating cancer.

The pancreas becomes of surgical interest when by reason of jaundice the life of the patient is threatened or when the etiology of the affection is believed to lie in some infection of the biliary tract which may be relieved by operation. Chronic pancreatitis may be concomitant with arteriosclerosis, syphilis or tuberculosis or may be associated as an indurative process with cirrhosis of the liver or the chronic nephritis of chronic alcoholism. A certain degree of chronic pancreatitis is associated with pancreatic calculi and carcinoma of the pancreas and with adherent deep ulcers of the stomach. Judd (1921) found that of a total number of 1290 patients with disease of the gallbladder and bile duct 347 (26.8 per cent) had associated pancreatitis. In attempting to diagnose chronic pancreatitis the symptomatology of all attacks of upper abdominal trouble which the patient may have had over a period of years must be considered.

Symptoms.—The symptomatology is grouped about pain, digestive disturbances and jaundice. Mostly the patients complain of attacks of dull boring pain in the epigastrium, sometimes referred to the right or left costal margin, back and shoulders. Rarely it is intense and has been mistaken for angina pectoris. Hinton believes that recurrent attacks of pain in the upper abdomen following cholecystectomy are sometimes due to an acute exacerbation of chronic pancreatitis lighted up by the operative procedure. Some of these patients undergo spontaneous recovery.

Sometimes there is merely discomfort after eating, especially of carbohydrates. *Bloating* may occur some hours after taking food and may be preceded by epigastric discomfort. *Constipation* is more frequent than diarrhea and the latter never becomes chronic. Loss of weight and strength is frequent and naturally suggests malignant disease. A moderate anemia is usually present. *Jaundice* is not common as a visible symptom but when the sclerosed head grips the common duct it may slowly progress to a deep greenish hue and simulate the jaundice of malignant disease. The intermittent character of jaundice due to a stone in the common duct must be considered. But even in pancreatitis the jaundice is rarely so tight as to cause the disappearance of bile from

the feces. Only rarely is the enlarged pancreas felt by palpation and then only in thin persons.

Functional Tests.—Theoretically disease of the pancreas should so alter its function as to make a diagnosis of chronic interstitial pancreatitis relatively easy. But it is probable that unless the duct is blocked sufficient secretion enters the intestine to make the results of doubtful value in the early stages. Tests for pancreatic efficiency can include only examination of the feces for the presence of undigested protein, excessive quantities of fat or free starch. Estimation of the blood sugar and the icterus index may be helpful.

Treatment.—From the surgical standpoint the treatment of chronic pancreatitis is based on removal of chronic infection of the gallbladder or gallstones by cholecystectomy, drainage of the common duct or diversion of the bile by cholecystogastrostomy or cholecystoduodenostomy. In cases of chronic disease of the biliary tract the surgeon must decide whether or not there is concomitant enlargement of the pancreas and in such cases should drain the common duct for a few weeks. If there is any suspicion that carcinoma is present the gallbladder should be preserved and anastomosed to the stomach or duodenum. Medical treatment of any underlying factor is essential.

PANCREATIC CALCULI

Etiology.—Because of the rarity of the condition and the difficulty of diagnosis pancreatic calculi are seldom recognized except at autopsy. The manner of their formation is probably similar to that of salivary calculi, a combination of stasis and infection. The common occurrence of gallstones and the rarity of pancreatic calculi are significant. They may lie in any part of the duct but are most common in the head of the pancreas. Complete obstruction of the duct results in atrophy and sclerosis of the parenchyma but the islets remain free from involvement. Retention cysts and abscesses are rare.

Symptoms.—The symptoms are not distinctive and are suggestive of chronic pancreatitis except that pain in the epigastrium is more marked and may radiate to the left

Jaundice and loss of weight have been observed. Positive functional disturbance of the pancreas is rarely noted in the cases reported with operation (Seeger 1925). As the substances composing the stone—calcium magnesium etc.—are radiopositive roentgen examination is important especially if the shadows are located behind the stomach in lateral views. The condition most frequently confused with pancreatic calculi is cholelithiasis. If the symptoms are those of stone colic and if gallstones are not found

gastrocolic omentum. All of these operations are rather difficult.

PANCREATIC CYSTS

Etiology and Types.—Cysts of the pancreas are comparatively rare and many of the reported cases classed as arising from the pancreas probably have arisen independent of this organ. Retention cysts have been ascribed variously to chronic pancreatitis, pancreatic calculi, gallstones or tumors. Proliferation cysts resemble the cystadenoma of the thyroid or ovary. Hydrated and dermoid cysts have been observed. Hemorrhagic cysts have been noted after trauma. Pseudocysts have no epithelial lining and lack the pancreatic ferment. They are collections of fluid in the region of the gland after inflammation or trauma. The various types are difficult to differentiate at operation.

Fig. 619.—The relations of a cyst of the pancreas to the abdominal viscera. The most common site is exemplified in the next three figures; the situation shown respectively in a and b is very infrequent.

the surgeon should not neglect to palpate the pancreas. A feeling of crepitation is said to be suggestive.

Treatment.—Calculi of any size and causing or probably causing obstruction should be removed by operation. The duct of Wirsung in the head of the pancreas may be reached by mobilizing the duodenum. The tail of the pancreas can be reached through the transverse mesocolon with proper protection of the middle colic artery. The body of the pancreas can be reached through an incision in the gastrohepatic or

nomia of the thyroid or ovary. Hydrated and dermoid cysts have been observed. Hemorrhagic cysts have been noted after trauma. Pseudocysts have no epithelial lining and lack the pancreatic ferment. They are collections of fluid in the region of the gland after inflammation or trauma. The various types are difficult to differentiate at operation.

The fluid content of the cyst is usually brown, probably from blood, but occasionally is clear. It is viscid and may contain

* Judd, Mallon and Malmer: *Arch. Surg.* 62

seem for advice and is often thought to be due to catarrhal jaundice or to the usual painless obstruction of the common duct by stone.

Pain is a symptom of importance and is usually colicky at first is epigastric and is often referred to peptic ulcer or gallstones. Later it becomes dull and constant and is referred to the back. Speed (1920) remarks that after an operation for relief of jaundice (such as cholecystoduodenostomy) the pain is relieved in most instances. This would bespeak the importance of dilatation of the gallbladder and ducts as a cause of the pain.

An epigastric tumor may be detected but great rigidity of the upper rectus muscle appears rather early and often obscures negative palpation even when emaciation has produced a scaphoid abdomen falling sharply away from the costal margin. This is especially true in large-framed men with a broad deep upper abdomen. In other patients the mass can be felt but is apt to be a conglomerate affair composed of the growth in the pancreas lymph nodes and omentum. It does not move with respiration and the extension of the liver is usually fixed. A sign of great importance is the finding of a greatly distended gallbladder which moves with respiration. In the presence of jaundice this is significant of obstruction other than stone (Courvoisier's law). Stone in the common duct almost always is preceded or accompanied by chronic cholecystitis with thickening of the walls of the gallbladder which prevents dilatation.

The roentgen findings are not significant except that an increase in the size of the duodenal curve or a smooth defect in the outline of the stomach may suggest an adjacent tumor. Cholecystography is not important because failure of visualization of the gallbladder is usual in obstructive jaundice.

The most important lesion for differential diagnosis is chronic pancreatitis but the distinction cannot be made in the early stages of carcinoma. Even with the abdomen open surgeons have made the mistake of taking one for the other. The lesions of chronic pancreatitis and carcinoma of the pancreas sometimes resemble each other so closely that the differential diagnosis cannot be

made without removing a section of tissue for histologic examination. A previous history of infection of the gallbladder tract chronic and persistent would suggest the probability of pancreatitis. Courvoisier's law is an important point in diagnosis.

Treatment—As in carcinoma of most other parts of the body surgical removal offers the only chance for the patient. Only a few patients are seen early enough to offer hope for cure. However there should be few in whom an exploratory operation is not justifiable partly because of doubtful diagnosis and partly because if the case is deemed hopeless a sidetracking operation may be done for the relief of jaundice after which the patient will live about a year. Cholecystogastrostomy is preferred and is feasible gastroenterostomy should be added as assisting the comfort of the patient.

In the event that the carcinoma is confined to the pancreas the surgeon should be prepared to perform a radical removal. Therefore the patient should be carefully prepared against the event of a severe operation.

Whipple (1938) has adequately pointed out that carcinoma of the head of the pancreas can be treated by radical resection. He has pointed out that ampullar carcinoma removed by the one stage procedure carried with them a higher mortality than those removed by the two stage procedure. Transduodenal removal with reimplantation of the common duct carries with it the danger of peritonitis and duodenal fistula. Local removal in either one or two stages carries a higher mortality rate than the radical two stage procedure with resection of the duodenum common duct and pancreas and closure of the pancreatic stump.

The original operation as developed by Whipple consisted of cholecystogastrostomy division and ligation of the common duct and gastrojejunostomy at the first stage. Three weeks later the greater portion of the duodenum common duct and pancreas were removed with closure of the pancreatic stump. This operation carried with it the danger of rapidly developing cholangitis and hepatitis by reason of the regurgitation of gastric contents into the biliary tree during forceful contractions of the stomach. Tests of pancreatic function after recovery indi-

ated that this patient was able to utilize 80 per cent of the fat, and only 15 per cent was recovered in the stool.

A further modification of this operation consisted in ligation of the common duct immediately below the cystic duct with an

the cholecystojejunostomy (Fig. 620). A gastrojejunostomy is performed at the second stage, followed by excision of the descending and second portion of the duodenum, the ampulla with the lower end of the common duct and a wedge-shaped por-

XXXII. THE SPLEEN

The spleen is one of the most interesting organs of the body, because it is involved in many abnormal conditions and also because there is still much uncertainty about its functions in health and about its role in many diseases

Gross Anatomy—The spleen is located in the left hypochondrium and is covered by the ninth, tenth and eleventh ribs. Its average weight in the adult is slightly under 200 Gm. and it measures about 12 cm. in length, 7 cm. in breadth and 4 cm. in thickness. The diaphragm, stomach and left kidney are in contact with the surfaces of this organ.

REFERENCE

Callander C. L., *Surgical Anatomy*, ed. 2, Philadelphia, W. B. Saunders Co., 1939.

Histology—Within the peritoneal investment (tunica serosa) the organ is enclosed by a capsule of connective and muscular tissue (tunica albuginea). From the inner surface of this layer, trabeculae spread throughout the spleen and this network constitutes the framework of the organ. Secondary processes divide the lobes into lobules and even smaller compartments or splenic units.

The tissue of the spleen itself or pulp is composed mainly of reticulum cells and fibers and areas of lymphocytes. At frequent intervals the lymphocytes form compact groups known as malpighian bodies. The pulp also contains the cells normally found in the blood, since the escaping blood saturates the entire tissue.

The branches of the splenic artery enter the hilum and are accompanied by the veins running in the trabeculae. The arteries subdivide into arterioles or penicilli. A direct connection exists between the arterial capillaries and the venous sinuses. Kinsely has shown that the vascular system of the spleen is a closed one but that red blood cells can pass through stimulated or injured sinus walls. However, MacKenzie, Whipple and Wintersteiner have stated recently that the system is really open and that the pulp space is the primary vascular unit. They think that when the capsule and trabeculae contract, the structurally "open" circulation becomes a functionally "closed" circuit.

Physiology—The chief functions of the spleen are (a) formation of lymphocytes and monocytes—(b)

phagocytosis of bacteria, inert particles, white blood cells and probably platelets (c) destruction of erythrocytes, formation of bilirubin and thus storage of iron, and (d) storage of blood. Under excitement during exercise or after injection of adrenalin contraction of the spleen occurs and blood is forced into the circulation. This has been demonstrated in animals but not in man.

Some other functions attributed to the spleen but not proved, are formation of purines, production of a coagulating substance of the blood, regulation of blood cholesterol, production of an inhibitor of platelet formation and influencing of bone marrow function in general and production of immune substances.

In spite of the fact that the spleen has apparently many functions, its removal causes no permanent effects. Splenectomy in the normal mammal results in a mild temporary anemia, an augmentation of reticulocytes, an increase in the resistance of the red blood cells to hypotonic saline solution, cellular hyperplasia of the bone marrow and a marked rise in the platelet count. These changes are transitory since other organs of the body apparently take over the functions of the spleen. Despite suggestive animal experimentation, there is no evidence that removal of the spleen renders man less resistant to infection.

Pathology—In such conditions as Gaucher's disease, tuberculosis, Hodgkin's disease and leukemia characteristic lesions are found by microscopic examination. But in most splenic disorders or ailments in which the spleen is involved no specific abnormalities are seen. Congestion, anemia, atrophy, hyperplasia, metaplasia and fibrosis are the principal changes found and they appear in various combinations and proportions. In the case of the spleen, therefore, the pathologic findings in many conditions are not as important as functional and clinical changes. The lesions encountered will be described as each disorder affecting this organ is discussed.

REFERENCE

Klemperer P., *Pathologic Anatomy of Splenomegaly*, Am. J. Clin. Path. 6:99, 1936.

Classification—It is impossible to classify abnormalities and diseases involving the spleen in a simple and logical manner because the etiology in many cases is not known and because there is no relationship between the various pathologic states. From a surgical viewpoint three divisions may be made as follows:

A Conditions for which splenectomy is of decided value

- 1 Traumatic lesions and non traumatic rupture
- 2 Anomalies of position and mechanical accidents (torsion and a movable spleen)
- 3 Spherocytic hemolytic jaundice
- 4 Thrombocytopenic purpura
- 5 Congestive splenomegaly splenic anemia Bant's syndrome
- 6 Schistosomiasis
- 7 Abscess (certain cases)
- 8 Cysts and hemangiomas
- 9 Neoplasms
- 10 Aneurysm of the splenic artery
- 11 Chronic neutropenia
- 12 Any condition in which a large spleen causes mechanical distress and in which splenectomy is not contra indicated

B Conditions for which splenectomy is of possible value

- 1 Gaucher's disease
- 2 Erythroblastic anemia (Cooley von Jaksch)
- 3 Sickle cell anemia
- 4 Cirrhosis of the liver
- 5 Tuberculosis

C Conditions for which splenectomy is of no value

- 1 Syphilis
- 2 Amyloidosis
- 3 Kah's azur
- 4 Malaria (tropical splenomegaly)
- 5 Polycythemia vera
- 6 Leukemia
- 7 Hodgkin's disease
- 8 Hemochromatosis
- 9 Anomalies
- 10 Other diseases

Various other diseases, some of which belong under group C of the foregoing classification merit mention for instance Nicomann Pick disease thrombophlebitis of the

splenic vein cysticercosis echinococcosis, infection and Schneller Christian disease Still's disease histoplasmosis agnogenic myeloid metaplasia and the Felty syndrome

In some diseases the spleen may be somewhat enlarged but these do not fall into surgical classification except for the problem of differential diagnosis. Illustrations of such conditions are subacute bacterial endocarditis infectious mononucleosis and pernicious anemia. Enlargement of the spleen may occur as a result of sulfonamide therapy

Diagnosis—A correct diagnosis of disorders involving the spleen depends as in all diseases upon eliciting an adequate history performing a thorough physical examination and obtaining essential laboratory data. In many of the conditions under consideration special hematologic studies are necessary. These will be discussed under each disease.

Of paramount importance in the disorders in which splenomegaly occurs is the necessity for palpating this organ. Sometimes a very large spleen can be seen by inspection as it bulges from beneath the left costal margin into the abdomen. To be palpated a spleen must be at least twice normal in size. The patient must be relaxed and the examiner should begin palpating just above the brim of the pelvis working his way up to the costal margin in order not to miss a very large spleen. Flexion of the patient's thighs often increases relaxation of the abdominal wall. Breathing easily and deeply through the mouth and abdominal breathing if this can be performed without causing undue abdominal rigidity are desirable maneuvers. With the patient supine the examiner stands at the subject's right side places his left hand under the patient's left posterior lower costal region to support this area and uses the finger tips or the radial border of the index finger of the right hand parallel with the costal margin for palpation. If the patient can place his own left fist behind his back for support then both of the examiner's hands are free for palpation. An

other method which is of use is to turn the patient on his right side near the right edge of the bed thus permitting the spleen to fall toward the anterior abdominal wall the examiner kneels or is seated Of great importance in determining that the mass felt is the spleen is the definite palpation of a notch

Splenic puncture with aspiration of the contents has been advocated as a diagnostic procedure but there is grave danger of serious hemorrhage especially when the spleen is soft and acutely enlarged Of considerable value in diagnosis of splenomegaly is a flat plate of the abdomen with proper exposure If there is doubt in distinguishing between the spleen and the left kidney pyelography will be of assistance

A CONDITIONS FOR WHICH SPLENECTOMY IS OF VALUE

I Traumatic Lesions and Non Traumatic Rupture—Subcutaneous injuries are much more common than open wounds and may be caused by direct or indirect violence Subcutaneous injuries may be divided into (a) lacerations of the parenchyma without rupture of the capsule (contusions) and (b) laceration of the capsule (ruptures)

Hemorrhage may be delayed after injury This occurs in 14 per cent of all cases of rupture Fifty per cent show signs in less than seven days and 75 per cent show signs in the second week after trauma However some patients bleed months after trauma (in one case two years afterward) This delay is due either to the insertion of bloody coagula or omentum in the splenic wound (tamponade) or to a large subcapsular hemorrhage which ultimately bursts the detached capsule

In contusions there may be pain tenderness local muscular rigidity and an increase in the size of the spleen Rupture of the capsule may occur with internal hemorrhage The pain in all injuries of the spleen is often referred to the left shoulder (Kehr's sign)

Rupture of the spleen gives rise to the symptoms of hemorrhage and shock Some indication of accumulation of blood within the peritoneal cavity may be obtained by dullness on percussion due to large blood clots in the splenic region with sh

ness in the right flank (Ballance's sign) The roentgenologic findings of increased density in the left upper quadrant of the abdomen obliteration of the splenic shadow elevation or tenting of the left diaphragm and displacement of the stomach toward the right side with evidence of free fluid between the loops of intestine offer an additional useful diagnostic aid (Webb's sign) The greater curvature of the stomach often presents a jagged serrated appearance and in massive hemorrhages reflex gastric dilatation occurs The blood changes are often suggestive in that hemorrhage gives an early and rapid increase in the number of leukocytes not accompanied by a relative fall in the hemoglobin value and the red cell count

Death may occur rapidly or the hemorrhage may be temporarily arrested only to recur The prognosis is bad if the patient is treated conservatively Splenectomy is the operation of choice yet adhesions may render splenectomy impossible in view of the condition of the patient In such cases suture or packing may be attempted for small tears In a large wound clamps or ligatures may be placed on the pedicle to control bleeding and the operation completed after shock has been controlled by transfusions

Stab wounds which are usually inflicted from above are often in the lower left portion of the thorax consequently the pleura lung and diaphragm are frequently involved But the wound may involve the left hypogastric or lumbar regions In gunshot wounds the bullet enters the abdomen more often than the thorax Therefore injuries of the gastrointestinal tract and kidneys predominate as associated lesions The prognosis is serious even in relatively slight wounds in which hemorrhage is

and symptoms may be slight. Replenishment is inadvisable because of the danger of infection. An independent incision and delivery of the spleen through the original wound with debridement of this wound is the operation of choice.

Spontaneous rupture occasionally occurs in a diseased spleen without obvious trauma, especially in cases of typhoid fever, malaria, pregnancy and puerperal infection. The symptoms are pain, tenderness and rigidity due to the rupture and to the irritation of the peritoneum by extravasated blood and are generalized because of the intraluminal hemorrhage. Immediate splenectomy under local anesthesia alone or supplemented by light general anesthesia is indicated. Transfusion should be given as soon as the hemorrhage is arrested.

2 Anomalies of Position and Mechanical Accidents (Torsion and Movable Spleen).—The large majority of cases of movable spleen are noted in women who have borne children. The significant feature is the relaxation of the abdominal walls. In most cases the mobile organ is abnormally large as a result of malarial or some other type of splenomegaly. The abnormal mobility usually develops gradually, the ligaments becoming elongated.

Symptoms.—Mobility may give rise to a variety of symptoms as the result of pressure or traction on adjacent structures. Traction on the stomach may cause epigastric pain, nausea and vomiting; compression of the intestines, obstipation; adhesions between the spleen and parietal peritoneum

pain pressure on the uterus, uterine displacement and disturbance of menstruation. Rectal tenesmus may result from fixation in the pelvis.

If a movable spleen does not become fixed by adhesions, rotation on its pedicle or torsion may occur in which case violent symptoms may develop suggesting intestinal obstruction or a strangulated ovarian cyst.

Treatment.—Mobility which occasions no distress does not demand operation, yet the patient should be warned as to the dangers and kept under observation. If symptoms develop, operation is advisable and if torsion occurs, operation is imperative.

Although the immediate results of splenectomy are claimed to be favorable, the late results are uncertain. Splenectomy is the proper procedure since the spleen is often pathologic and since recurrence of torsion is usual. The operation is easy by reason of the elongated pedicle.

3 Spherocytic, Hemolytic Jaundice (Achloric Jaundice).—Spherocytic hemolytic jaundice is characterized by splenomegaly, achloric jaundice, anemia, a decreased resistance of red blood cells to hypotonic saline solution (fragility test), an increase of reticulocytes and a preponderance of microcytes which are spheroidal in stead of biconcave in shape.

While a congenital and an acquired type are generally described, doubt has been cast upon the existence of the latter. It is now known that adults may carry stigmas of the disease and show no signs and symptoms until some toxic or infectious episode precipitates an attack. Moreover, examination of the relatives of the patients with the 'acquired' type frequently reveals the typical traits of the condition.

The *etiology* is probably an inherited defect of the red blood cells which renders them small and globular so that they do not withstand the trauma of circulation. The role of the spleen in producing symptoms is probably due to the fact that the abnormal erythrocytes undergo increased damage in this organ.

Pathologically the spleen is enlarged and congested and has an increase of pigment as have also the liver, kidneys, bone marrow and lymph nodes. The sinuses of the spleen are empty and perisplenitis may be present.

sixty per cent of the patients have pigmented gallstones.

The symptoms and signs of spherocytic jaundice vary but the most common evidence of this condition is jaundice. Splenomegaly may be the first manifestation of the disease and may cause the patient abdominal discomfort. In some cases anemia is the most striking finding. Often acute attacks characterize the disorder. These crises are manifested by upper abdominal pain, nausea, vomiting, fever and an increase of anemia and jaundice. These attacks frequently follow an infection, fatigue or a gastrointestinal upset. Chronic ulcers of the legs may complicate the condition.

The laboratory findings are characteristic in spherocytic jaundice. The anemia is normochromic or moderately hyperchromic. The cells are macrocytic but their globular shape gives a higher volume index or volume thickness index than one usually obtains with small cells. This spherocytosis probably explains the decreased resistance to hypotonic saline solution (fragility) since these globular cells cannot swell as much as normal cells and therefore burst more readily. While normal red blood cells begin to hemolyze in 0.45 per cent saline solution and are completely laked in 0.3 per cent, the erythrocytes of these patients may begin to break up in 0.5 to 0.7 per cent and are often completely hemolyzed in 0.4 per cent. This constant destruction of red blood cells causes a marked increase in reticulocyte as evidence of excessive bone marrow function. During crises even nucleated red blood cells may be found in the blood. The reticulocyte count may vary from 5 to 15 per cent. Other laboratory changes are an increased icterus index, a positive indirect van den Bergh reaction, bilirubinuria, urobilin in the urine and an increase of urobilin in the stool. In children skeletal changes similar to those found in erythroblastic anemia are seen.

The diagnosis of this condition is simple in most cases but some patients lack one or more of the characteristic findings—*anemia, jaundice, splenomegaly, a change in the fragility curve or reticulocytosis.* Moreover Dameshek, Schwartz and Singer and also Thompson emphasize that there are hemolytic anemias which are atypical and may require different therapy than does true

familial spherocytic jaundice although showing many similar features.

The treatment of typical spherocytic hemolytic jaundice is splenectomy. In no other condition are such brilliant results obtained. In Thompson's series of 30 patients only 1 failed to recover and at autopsy many accessory spleens were found. While it is desirable not to operate during a crisis, reports of successful operation during such an episode have been published. It must be remembered that these patients often react poorly to transfusions because of increased hemolysis and resulting anuria. Therefore preoperative transfusions should be avoided if possible. If cholecystectomy is necessary it should be postponed for a subsequent operation. After splenectomy relief of symptoms is often immediate and the jaundice disappears in a few weeks. The anemia improves rapidly and progressively and all evidences of hemolysis may be gone by the time the patient leaves his bed. The abnormal reaction of the erythrocytes to hypotonic saline solution, however, persists except in a very few cases in which a return to a normal state has been reported. Spherocytosis also continues. This indicates that while splenectomy results in disappearance of the symptoms and signs it has no effect upon the basic abnormality.

4 **Thrombocytopenic Purpura.**—Thrombocytopenic purpura or Werlhof's disease is characterized by hemorrhages in the skin and subcutaneous tissues and from the mucous membranes of the nose, gums, gastrointestinal tract and endometrium. A marked reduction of platelets is found. The hemorrhagic areas may take the form of petechiae, ecchymoses or hematomas and the course of the illness may be acute, subacute, chronic or remittent.

twenty-four hours. In some cases after the postoperative increase of platelets there occurs a gradual fall to preoperative levels but in most of these patients hemorrhages do not reappear. Other methods of therapy such as frequent transfusions or irradiation of the spleen have also been advocated.

5 Congestive Splenomegaly (Splenic Anemia, Banti's Syndrome)—Congestive splenomegaly is a term suggested by Thompson and his co-workers as best fitting the group of conditions previously called splenic anemia and Banti's syndrome. It is characterized by splenomegaly, anemia, leukopenia and in many cases cirrhosis of the liver.

The *etiology* of the condition has been shown to be splenic vein hypertension caused by a variety of conditions. The most common reason for such hypertension is periportal cirrhosis of the liver of the Laennec type. Other causes of congestive splenomegaly given by Rousselot are schistosomiasis, miliary thrombosis of the splenic vein, cavernomatous transformation of the portal vein and stenosis of the portal vein. Direct measurement of splenic vein pressure at operation compared to arm vein pressure showed a marked increase in cases of congestive splenomegaly as compared with that of controls. No other etiologic factors have had as good experimental and clinical substantiation as has the concept of increased splenic vein pressure. The disease occurs more frequently in males and is found during early adult life as a rule. A childhood type has been described.

Pathologically the large spleen has a rough surface due to perisplenitis and a thick capsule. The cut surface is resistant, tough and reddish gray. The follicles are small and reduced in number. Microscopic examination shows marked fibrosis.

The splenic and portal vessels are frequently sclerotic and the sinusoids are dilated and empty. Portal cirrhosis is found in many cases. Ascites, perihepatitis and varicosities of the veins of the lower part of the esophagus and of the stomach appear later in the disease.

The *symptoms and signs* vary with the stage of the disease. Enlargement of the spleen may be the first evidence of the affliction. This and anemia may exist for years. Occasionally hematemesis may be the initial indication of illness. Later hemorrhages in the skin and from the mucous membranes occur and usually indicate that cirrhosis of the liver is well established. The liver may be large at first but later shrinks. Finally ascites, loss of weight and some jaundice develop. In patients with a patent umbilical vein distended umbilical veins, a venous thrill and murmur may occur (Cruveilhier-Bavergarten syndrome).

The *laboratory findings* depend upon the particular stage of the disease. Early in the course a moderate normocytic anemia is present. In case of hemorrhage a microcytic hypochromic anemia results. Hepatic damage is frequently characterized by macrocytic anemia. This however does not respond well to liver extract therapy. Leukopenia and thrombocytopenia are usually present. A slight increase in the resistance of the erythrocytes to hypotonic saline solution is often seen. The coagulation and bleeding times may be normal. The tourniquet test positive and the reticulus index somewhat elevated. The van den Bergh reaction is indirectly positive and in the later stages a positive direct reaction may be obtained. The urine contains urobilin and at times small quantities of bilirubin.

The *diagnosis* depends upon eliminating other causes of splenomegaly. As a rule splenomegaly with anemia, leukopenia and thrombocytopenia suggests congestive splenomegaly.

The *treatment* of this condition in its early stages is splenectomy. When cirrhosis

advanced the results are poor. Howells and Burg and Dulin have reviewed the results of splenectomy in their series of cases and while Howells does not believe that the operation prolongs life, Burg and Dulin feel it is the treatment of choice certainly in early cases. Ligation of the gastric coronary veins should be attempted if possible at the time of operation. The operative mortality varies from 7 to 10 per cent. Omentopexy may be tried to promote collateral circulation when cirrhosis and ascites are present. Transfusions, liver extract and vitamin B therapy are valuable adjuvants. Diuretics should be used for ascites and if they are unsuccessful paracentesis is indicated. Because of the danger of recurrence of hemorrhages, alcohol, condiments, excessive roughage and very hot foods should be avoided. Violent straining may also be dangerous. Hemorrhage in the presence of marked hepatic damage cannot be prevented by vitamin K administration because prothrombin cannot be manufactured.

6 Schistosomiasis.—Patients suffering from infestation by blood fluke, are prone to enlargement of the liver and spleen (Egyptian and Columbian splenomegaly). The enlargement is due to cirrhosis and the splenic lesion is secondary. With the establishment of the hepatic cirrhosis, ascites, cachexia and gastrointestinal disturbances, the typical so-called Bant's disease of the Orient is recognized.

7 Abscess.—Although abscess of the spleen is an infrequent lesion it occurs far more often than operative statistics indicate. As a complication of infectious diseases it is frequently overlooked. The condition usu-

ally occurs as a metastatic abscess occasionally as an infected hematoma and rarely as a direct extension of an adjacent suppurative process. Finally there may be no demonstrable cause. Any infectious disease such as typhoid fever, puerperal sepsis, pneumonia and localized suppurative processes may be the cause of a secondary splenic abscess. A characteristic feature of splenic abscesses is their marked tendency to form sequestra that is large necrotic masses of splenic tissue.

Symptoms and Diagnosis.—The clinical picture of splenic abscess is usually rather indefinite. It is not until the capsule is involved in the inflammatory process that the presence of the abscess manifests itself by pain due to perisplenitis. It often radiates to the left scapular region. Irregular chills and fever of an intermittent type are fairly constant. Enlargement of the spleen and tenderness on pressure may be noted. Abscesses in the upper segment often give rise to the symptoms of subphrenic abscess and are apt to be overlooked in consequence of the early involvement of the left pleura. Suppurative pleurisy may ensue and the original focus may be readily overlooked. The diaphragmatic movements on the left side are often absent as shown by fluoroscopy. Leukocytosis is usual but not constant but a marked increase of immature polymorphonuclear cells is always present. In doubtful cases exploratory puncture may be employed.

Prognosis.—In the absence of timely surgical intervention the prognosis of abscess of the spleen is unfavorable. On the other hand early operation is often followed by excellent results.

Treatment.—In most cases drainage of the abscess cavity has been performed but a considerable number of successful cases of splenectomy for splenic abscess have been reported. Schmeisser and Harris reported 29 cases of multiple necrosis of the spleen due to vascular thrombotic and infectious causes. Sulfonamide or penicillin therapy should be instituted.

8 Cysts and Hemangiomas—Cysts of the spleen are rare but since they give rise to symptoms in a comparatively silent region of the abdomen—the left hypochondrium—a discussion of them is warranted. They may be divided for purposes of classification into the parasitic and non parasitic varieties.

McClure and Altemeier have classified cysts as follows:

- I True cysts—lined by specific secreting membrane
 - A Epithelial
 - 1 Dermoids
 - 2 Epidermoids
 - B Endothelial
 - 1 Vmphangioma
 - 2 Hemangioma
 - 3 Polycystic disease
 - 4 Simple serous cysts
 - C Parasitic—lined by protoplasmic matrix containing numerous nuclei
 - 1 Hydatid cyst caused by *echinococcus*
- II False cysts—no specific secreting lining
 - A Hemorrhagic
 - B Serous
 - C Inflammatory
 - 1 Acute necrosis in infection
 - 2 Chronic tuberculosis
 - D Degenerative liquefaction of infarcted areas caused by embolism or arterial thrombosis

Non parasitic cysts of the spleen occur most often in women of the child bearing age. Contributing causes are splenic diseases and trauma. The wall of the cyst is lined either with fibrous tissue or with cells of mesothelial or endothelial origin.

Parasitic cysts of the spleen occur in about 2 per cent of cases of hydatid disease. They are large and multilocular and are lined with the echinococcus membrane the inner layer of which contains larval scolices. In addition to the general symptomatology of a mass in the left hypochondrium of diagnostic import the complement fixation test, a precipitin test and microscopic examination of the cystic fluid for hooklets are important.

Pressure symptoms arise in cases of either variety of cysts. Pain in the left hypochondrium is often associated with vague indigestion, weakness and anemia. Swelling in the left hypochondrium with extrinsic dis-

tortion of the splenic flexure visible in the roentgenogram must bring a diagnosis of splenic cyst into consideration. A bruit heard over the left hypochondrium is the classical sign of a hemangioma.

9 Neoplasms—New growths of the spleen are uncommon. Secondary metastases are rare because of the spleen's contractility and its paucity of lymphatics according to Warren and Davis but Herbut and Gabriel report 23 cases. Tumors of the spleen may be classified as follows:

- (a) Benign fibroma lymphoma hemangioma lymphangioma chondroma osteoma
- (b) Malignant angiosarcoma lymphosarcoma reticulum cell sarcoma

Goldberg has published a review on primary splenic neoplasms and recently Hausmann and Gaarde summarized the literature dealing with malignant neoplasms. Sweet and Warren described a benign tumor which they called a splenoma or hamartoma of the spleen.

The rapid growth of a hard mass in the left hypochondrium should suggest a neoplasm especially if a nodular surface is felt. Early splenectomy is the only hope for a cure. At operation the pedicle should be ligated before any manipulation is done so as to prevent displacement of tumor cells into the circulation. When splenectomy is impossible irradiation may be employed.

10 Aneurysm of the Splenic Artery —

This is a rare condition but has been diagnosed preoperatively. Since Crisp's report in 1847 less than 100 cases have been recorded. This condition has been reported as a complication of pregnancy. Rupture frequently occurs. Arteriosclerosis, neoplasm of the pancreas, embolism, syphilis or trauma has occasionally been found to be the cause of aneurysm, but often no reason for the lesion is revealed at autopsy. The patient complains of vague distress in the left upper portion of the abdomen. Pulsation or a faint bruit is rarely noted. In performing splenectomy it is advisable to ligate the splenic vessels proximal to the aneurysm as a pre-liminary step.

B CONDITIONS FOR WHICH SPLENECTOMY IS OF POSSIBLE VALUE

1 Gaucher's Disease —

Gaucher's disease is a chronic familial and sometimes congenital disturbance of lipid metabolism in which certain cells of specific significance and morphology appear in the spleen, liver, lymph nodes and bone marrow. These so-called Gaucher cells have their origin through the deposition of a cerebroside-keratin in the reticulum and histiocytic cells of these organs. They appear in no other disease.

The cells are very large and have psyknotic

and sometimes multiple eccentric nuclei. The cytoplasm is made up of a fibrillar network which gives it a wrinkled appearance. The kersin containing cytoplasm does not stain with the fat stains and is not doubly refractile. Masses of Gaucher cells account for the white speckling of the spleen and hepatic substance as well as the nodular infiltration of lymph nodes and bone marrow. The latter along with the increased porosity and thinning of the cortex without cortical infiltration gives a recognizable roentgenologic entity.

Clinically Gaucher's disease shows progressive and marked splenomegaly with out ascites and lesser hepatic enlargement and a visible lymphadenopathy. Hypochromic anemia and leukopenia are constant findings in the peripheral blood. Thrombocytopenia and the hemorrhagic diathesis are frequently present late in the course of the disease. Of variable occurrence are brownish yellow pigmentations of the exposed skin, pterygium like thickening of the ocular conjunctiva, spastic tremors and convulsions, and unique changes in the bones in persons constitutionally predisposed to them. The onset of the disease is most frequent in persons under the age of forty, the maximum incidence being under five years of age and between the ages of twenty five and thirty five. The course may be rapid with marked splenomegaly and hepatomegaly or it may run for twenty years or more. The most frequent termination is intercurrent infection. Tuberculosis is not infrequently responsible.

The diagnosis can be established frequently by splenic or marrow puncture for identification of the specific cells, biopsy of a peripheral lymph node or roentgenologic examination of the bones.

The treatment of Gaucher's disease is symptomatic inasmuch as knowledge of its cause is still incomplete. Splenectomy obviously holds no hope of cure. A large hardensome spleen, thrombocytopenia and the hemorrhagic diathesis may be considered as indications for palliative removal of the spleen. In spite of the high mortality reported by some authorities and the chronicity of the disease in some cases without operation it is generally considered that splenectomized patients have a longer and more comfortable life.

2. Erythroblastic Anemia (Cooley, von Jaksch).—In 1889 von Jaksch described a chronic anemia of childhood in which there developed pronounced changes in the shape and size of the red blood cells, a large hard spleen, some hepatic swelling and leukocytosis. Many childhood anemias classified as this condition have subsequently found a place in hemolytic icterus, splenic anemia, leukemia, etc. There remains a group, however, different from the rest but having essential features in common which Cooley definitely identified and called erythroblastic anemia. Von Jaksch's description failed to include quite a number of its characteristics.
- This is a rare congenital and sometimes familial disease of children of Mediterranean races. Therefore Whipple and Bradford call it thalassaemia (Mediterranean anemia). The onset is in the first few years of life, the course is chronic and progressive and the termination is usually fatal. The fundamental disorder is apparently one of abnormal hematopoiesis. The most common characteristics of the disease have been fully described by Baty, Blackfan and Diamond and may be enumerated as follows: enlargement of the ribs and cranial bones imparting to the child a mongolian facies; progressive enlargement of the abdomen because of marked splenomegaly and a lesser hepatomegaly; pallor, subicteric tint or jaundice of the skin, mild generalized enlargement of the peripheral lymph nodes and generalized skeletal changes visible in the roentgenograms and comprising cortical thinning, increase in the width of the bones, increased porosity and thickening of the medullary trabeculations. The changes in the bone marrow consist of marked hyperplasia of the erythroblastic elements and to a much less degree hyperplasia of the myeloid elements so that the marrow is almost identical with that in pernicious anemia during a relapse. The peripheral blood shows a tremendous increase in young nucleated red cells (the number often reaching many thousands), a moderate anemia of low color index, anisocytosis, poikilocytosis and achromia of the red cells and a constant leukocytosis, the count averaging 20,000 with a predominance of the myeloid series and a few young forms.
- Abnormal hemolysis is reflected in a positive indirect van den Bergh reaction usually a mildly elevated icteric index and an increased urobilinogen output in the stool and urine, although there is no increased red cell fragility to hypotonic saline solution. The spleen is enlarged up to six times its normal size and microscopically shows extramedullary hematopoiesis of the erythroblastic series and a lesser myeloid response. The liver exhibits like changes to a much less extent.
- One of the distinguishing features of the disease is the normoblastic reaction to splenectomy, the count frequently exceeding 100,000. This number gradually falls but the essential blood picture remains unaltered. Thus, as in many splenomegalic splenectomies, is of little curative value but as a palliative measure it relieves the growing child of the harrowing burden of progressive splenomegaly and there is evidence that this may actually retard the progress of the disease and prolong life. There is also an adult type of this Mediterranean disease which is familial and which is characterized by a low hemoglobin and relatively high red blood cell count, sometimes polycythemia, stippling, target cells and splenomegaly.

3 Sick Cell Anemia—Sickle cell anemia is an inherited disease found chiefly in Negroes but has also been reported in other races. Many individuals show sickle cells but only about 1 in 40 actually suffers from anemia. In early life the spleen is large but becomes fibrotic and soon atrophies. The chief symptoms are weakness, dyspnea and ulcers on the legs. In children changes occur in the skull similar to those seen in erythroblastosis. Complications due to cerebral vascular thrombosis are not uncommon. Abdominal crises, joint pains, attacks of jaundice and fever are frequent. The main laboratory findings are anemia, usually normocytic in type, an increased icterus index and serum bilirubin, a positive indirect van den Bergh reaction, urobilinuria, reticulocytosis, occasionally nucleated red blood cells in the peripheral blood, leukocytosis with an increase of immature polymorphonuclears and thrombocytosis. Most important of all in the diagnosis is the presence of sickling best demonstrated by moist preparations in decreased oxygen tension.

There is considerable difference of opinion about the efficacy of splenectomy in sickle cell anemia. Operation during a crisis should be avoided.

4 Cirrhosis of the Liver—In cirrhosis of the liver, enlargement of the spleen is constant, this being due to increased splenic venous pressure. When the spleen enlarges markedly, the condition is essentially congestive splenomegaly, which has been described previously. Although splenectomy cannot affect the liver directly, removal of the spleen reduces the amount of blood in the portal circulation and reduces the load upon the liver. If regeneration of hepatic tissue is possible with the aid of vitamin therapy, splenectomy from a theoretical viewpoint at least might be logical. How-

ever such a procedure would be of value only in the early stages of cirrhosis. Omentopexy to provide compensatory circulation in the presence of ascites is not performed frequently now.

5 Tuberculosis—Tuberculosis of spleen may be primary or secondary. The latter type is relatively frequent and is not amenable to surgical treatment. Winteritz collected reports of 51 cases of marked involvement of the spleen. The most common features of the condition are pain and enlargement of the spleen with the symptoms of general malaise. Occasionally the symptoms are those of an acute infection. The blood picture may resemble that found in congestive splenomegaly or thrombocytopenic purpura. Healed tuberculosis of the spleen has not only been found at autopsy but calcified areas have been demonstrated by x-ray. If no tuberculosis is evident elsewhere, splenectomy is indicated in tuberculosis of the spleen. Several cases have been reported with successful results.

C CONDITIONS FOR WHICH SPLENECTOMY IS OF NO VALUE

There are many splenomegalic conditions which merit mention principally because they must be differentiated by the surgeon from disorders for which splenectomy is of

value These diseases will be described briefly

1 **Syphilis**—Splenomegaly occurs usually in the tertiary stage of syphilis and is characterized by fibrosis or gummas In the florid secondary stage the spleen may be palpable As a rule antiluetic therapy is the treatment of choice However when the large spleen causes symptoms for mechanical reasons splenectomy may be considered This should be followed by vigorous specific therapy Occasionally splenomegaly with gastric hemorrhage is encountered In such cases splenectomy is desirable

REFERENCE

Starr G E Splenectomy for Gastric Hemorrhage in Splenomegaly Associated with Syphilis Case Reports U S Naval Med Bull 37:256 1939

2 **Amyloidosis**—Amyloidosis affects the spleen more commonly than it does any other organ The amyloid material is a protein which takes a walnut or mahogany brown color when stained with iodine The condition is secondary to chronic infection elsewhere in the body such as tuberculosis or osteomyelitis The congo red test is used for diagnosing amyloidosis and depends upon the fact that amyloid in the tissues takes up the dye and retains it for long periods

3 **Kala Azar**—Kala azar is caused by a protozoan *Leishmania donovani* which is found in the spleen liver and blood and in the cells of the reticuloendothelial system The condition occurs mostly in eastern Asia The chief features of the disease are irregular fever weakness dark pigmentation of the skin enlargement of the spleen and liver anemia leukopenia sometimes granulocytopenia and thrombocytopenia Pentavalent antimony compounds are used for treatment Splenectomy is not indicated

4 **Malaria (Tropical Splenomegaly)**—Enlargement of the spleen is but one of the evidences of chronic malaria The disease is not located exclusively in the spleen nor is that organ an incubator for the malarial parasite Therefore the removal of the chronic malarial spleen will not bring about a cure of the infection On the contrary it may stir into activity an infection which has apparently been cured Recently malaria has become common among drug addicts be-

cause of the transference of the plasmodia from an infected patient by the use of an unsterilized needle and syringe To the surgeon malarial spleens are of importance because rupture may occur after slight trauma or even spontaneously

5 **Polycythemia Vera**—Polycythemia is found most frequently in adult males and is characterized by a marked increase in the red blood cell count (varying from 8 000 000 to 11 000 000) cyanosis and splenomegaly Secondary polycythemia may occur in congenital heart disease pulmonary arterio sclerosis (Ayerza's disease), thrombosis of the splenic vein and in many other conditions A hypertensive type and a congenital form also occur In polycythemia vera a marked increase in the formation of red blood cells by the bone marrow is the cause of the polyglobulism Phlebotomy, x-ray therapy acetylphenylhydrazine and Fowler's solution are the therapeutic measures used

REFERENCE

Reznikoff P Polycythemia in Nelson's Loose-Leaf Medicine New York, Thomas Nelson & Sons 1941

6 **Leukemia**—Splenic enlargement is found in all types of leukemia The disease occurs at all ages and is characterized by widespread disorderly proliferation of leukocytes with an apparent arrest of maturation In typical cases the white blood cell count is high sometimes running up to several hundred thousand Anemia is often present In myelocytic leukemia the bone marrow is hyperplastic Lymphocytic leukemia affects the lymphoid tissue and monocytic leukemia involves the reticuloendothelial system The average length of life in chronic leukemia is about three years Acute leukemia may prove fatal in a few weeks or months and patients suffering from this type of disease may never show any appreciable enlargement of the spleen Therapy is usually some type of irradiation Fowler's solution may be used in myelogenous leukemia

REFERENCE

Forkner C F Leukemia and Allied Disorders New York Macmillan Co., 1938

7 **Hodgkin's Disease**—Hodgkin's disease is a chronic granulomatous process involving the lymphoid tissue The earliest

change in the lymph nodes is a hyperplasia of lymphoid cells. Later the lymph nodes lose their characteristic structure and the tissue is filled with closely packed cells among which plasma cells, epithelioid cells, eosinophils and Dörrth-Reed-Sternberg cells are found. Fibrosis occurs later. The spleen is enlarged in the majority of cases and occasionally is very large. Splenic Hodgkin's disease may be characterized by a remittent fever; this is called the Pel-Ebstein type. The etiologic factor is unknown. A few instances have been reported in which the splenic enlargement apparently was the only clinical evidence of the disease. Splenectomy would be indicated in primary splenic Hodgkin's disease if the diagnosis could be made.

- Jaeger, H. Jr. Report on Medical Progress: Hodgkin's Disease and Allied Disorders. New England J. Med. 240:6, 1937.

8. **Hemochromatosis.**—Hemochromatosis is characterized by pigmentation of the skin and viscera, diabetes and hepatosplenomegaly. A diffuse deposit of hemosiderin is found in the organs and lymph nodes. The spleen is fibrotic and the liver cirrhotic.

REFERENCE

- Flaum, G., and Stack, C. H., Jr. Hemochromatosis: Report of a Case with Necropsy and Analysis of the Liver. Arch. Int. Med. 67:133, 1937.

9. **Anomalies.**—Complete absence of the spleen occurs rarely but is compatible with health and longevity. Microplasma, multiple or accessory spleens (usually situated near the hilum), lobulation, congenital hernia of the spleen through the diaphragm and transposition of the spleen to the right side in situs transversus are anomalies which have been described in the literature.

10. **Other Diseases.**—Many diseases are accompanied by some splenic enlargement. In disorders like Niemann-Pick's disease and Hünd-Schüller-Christian's disease (two conditions which are similar but show distinct differences from Gaucher's splenomegaly) and in Lederer's anemia (an affliction characterized by fever and hemolytic anemia) the spleen may show considerable increase in size. In infection in congestive heart failure and sometimes in pernicious anemia the spleen may be palpable. This is especially

true in subacute bacterial endocarditis. In infectious mononucleosis often presents splenic enlargement.

Infarction of the spleen is not infrequent. It may occur in infectious conditions giving rise to a septic infarct terminating in an abscess. Local pain is usually present especially if perisplenitis develops.

Still's disease is seen in children and the picture is one of chronic infectious arthritis with hyperplasia of the lymph nodes, enlargement of the spleen and liver, normocytic anemia and frequently leukopenia. It is a syndrome is a splenomegaly condition in adults resembling Still's disease but recently the existence of such a condition has been questioned by Tulko, Bauer and Short.

OPERATIVE PROCEDURE

Surgical diseases of the spleen are usually best treated by splenectomy since its affections commonly involve the entire organ or if local as in injuries, cysts or tumors the attempt to substitute lesser procedures is attended by greater danger than removal of the entire organ. In addition splenectomy has been advocated and performed in cases of total or subtotal pancreatectomy of total gastrectomy and of partial gastrectomy by the thoracic route to secure better exposure. The operation may be of great simplicity or of the greatest difficulty. Hemorrhage is the chief danger. Injury of the pancreas or the adjacent stomach has often occurred and can be obviated only by adequate exposure.

and care. It is wise always to have a donor present for immediate transfusion if necessary. Any incision may be used which gives adequate exposure but it is essential that complete control of the operative field is assured before the spleen itself is attacked.

The chief difficulties are usually due to the presence of highly vascular adhesions and to the development of exceedingly large thin walled veins which are easily ruptured and bleed copiously thus obscuring the field. When these complicating conditions are absent as in the ordinary case of traumatic rupture with a normal spleen or in

doubly ligating and dividing all available vessels before attempting to mobilize or dislocate the spleen. If the pedicle can be secured before the spleen is stripped from its high attachments the operation is rendered much safer. In certain cases however, it is simpler to separate the spleen posteriorly and superiorly and introduce a large moist hot pick into the vault of the diaphragm applying pressure to control the venous oozing while the pedicle is isolated and secured. The spleen in this procedure is rolled inward (turned turtle) exposing the posterior aspect of the pedicle. It should never be at

Fig. 621—Ligation of splenic pedicle.

the case of a wandering spleen or in the earliest stages of splenomegaly it is a simple matter to secure the pedicle as the first procedure thereby insuring control of any hemorrhage that may occur. Under these conditions after the bloodless peritoneal attachments of the gastrosplenic omentum and lienorenal ligament have been severed the pedicle may be grasped at once with crushing clamps and ligated en masse or it may be compressed by a rubber-covered clamp and the vessels ligated separately. When adhesions and large thin walled veins are present it is essential to proceed cautiously

tempted until all available vessels at the lower pole have been secured.

After removal of the spleen the cavity should be carefully inspected and if possible all oozing surfaces or bleeding vessels that cannot be separately clamped secured by oversewing with catgut ligature the so called snaking suture. In some cases it is necessary though never desirable to leave a pack in place covering the oozing surface. Occasionally inaccessible vessels must be clamped and the clamps left in place for two or three days before removal.

• Balfour Surg. Gynec. & Obst. 23

If an accessory spleen or spleens are present, these should be removed in case of diffuse splenic disease. If ascites is present, the fluid should be completely removed before the spleen is treated. No drainage is necessary unless tamponade for bleeding is indicated.

Other Operative Procedures—An ectopic or wandering spleen may be treated by splenopexy if the organ is small and apparently normal. In this operation the posterior parietal peritoneum is incised transversely just below the diaphragm and a pocket made by stripping the peritoneum from its posterior attachments. Into this the lower pole of the spleen is inserted and secured by ligature. It is usually better to perform splenectomy for this condition. Splenorrhaphy is occasionally feasible to check hemorrhage from small traumatic ruptures. Ligation of the splenic artery has been carried out in a few instances in splenomegaly but is not recommended, because of the danger of necrosis of the spleen and the uncertainty of the results on splenic disease. Occasionally resection of the spleen may be feasible for small accessible cysts and benign tumors. It is, however, rarely indicated, and the dif-

ficulty of controlling bleeding by suture of the spleen will always make its adoption of doubtful propriety. Splenotomy, or incision of the spleen, for abscess is advisable in those cases in which the spleen has attached itself by inflammatory adhesions to the abdominal wall.

XXXIII HERNIA

GENERAL CONSIDERATIONS

Definition—The protrusion of any viscus from the cavity in which it normally belongs through either a natural or an acquired opening is called a hernia or in older parlance a rupture.

General Considerations—Abdominal hernias are named according to the location of the hernial ring, thus inguinal femoral umbilical epigastric lateral ventral lumbar sciatic obturator perineal and pudendal. The viscera involved are in order of frequency omentum intestine and urinary bladder although in rare cases other abdominal or pelvic organs may be encountered. All these are external hernias.

The internal hernias are usually due to some congenital anomaly in development and include hernia into the fossa of Treitz the foramen of Winslow the intersigmoid fossa and the pericecal fossae. Diagnosis is occasionally made by x-ray before operation but usually during operation for intestinal obstruction. Diaphragmatic hernia occurs either through congenital defects or through rents due to trauma and penetrating wounds.

Relative Frequency—According to the statistics on a large series of cases reported from different clinics, ventral hernia constitutes 80 per cent of all abdominal hernias, umbilical 10 per cent, femoral 8 per cent, epigastric 3.8 per cent, sciatic 0.7 per cent, and all other types together less than 1 per cent.

The inguinal, the femoral and the umbilical hernias occur through natural apertures provided for the emergence of important blood vessels and other structures and similarly the sciatic the obturator and others of the less common hernias may be accounted for under the theory that hernia occurs through a fascial defect or hiatus provided for the passage of blood vessels.

Mosely and Sizoo accept the Lippman theory of Cloquet as the best explanation for epigastric hernia and of hernia in the semilunar line also called lateral ventral or Spigel's hernia. The outgrowth or protrusion of a preperitoneal lipoma through the fascial hiatus along side some small vessel may later drag a funnel of peritoneum into it forming a true hernial sac. Owing to the tilting forward of the pelvis accompanying the erect posture of man the lower abdominal wall is

subjected to strains and pressures which are lacking in quadrupeds.

In the human canal as in no other hernial region embryonic development not only has provided a defect in the parietes but actually forms a potential hernial sac of peritoneum as the processus vaginalis peritonei is dragged to the bottom of the scrotum in the male or as the canal of Nuck is carried out with the round ligament into the vaginal canal of the female. Although this vaginal process normally becomes sealed off shortly before or after birth Sir Arthur Keith states that in 50 per cent of male infants it remains open up to the fourth month. The number of males who go through life with a patent funicular process which means a potential hernial sac is stated by Russell to be 10 per cent and by Sachs to be 20 per cent. By no means all of these susceptible persons ever have a hernia for this only when omentum or intestine has protruded into the patent process that a hernia can be said to exist. Keith has shown that the conjoined internal oblique and transversalis muscles under reflex nervous mechanism act against the fixed *Ligamentum inguinale* in the manner of an inguinal shutter which serves to close the internal inguinal ring against internal stress.

Factors Involved in the Etiology of Oblique Inguinal Hernia—These factors are (1) patency of the vaginal process due to congenital defect in closure (2) a sudden increase of intra-abdominal pressure as in coughing straining or lifting (3) a sudden strain which catches the inguinal shutter off its guard. Especially in the stooping position the conjoined muscles and Poupart's ligament are relaxed. Under these conditions omentum or intestine may be forced through the internal ring and a hernia may develop. This explanation is not accepted by all writers and there are some eminent surgeons who assert that hernia is not an acute surgical entity but in reality a progressive disease. They claim that a hernia never results from a single isolated strain because it is inconceivable that an elongated or pear-shaped sac could develop instantaneously from the parietal peritoneum but that repeated impulses over a long period would be required to hammer the peritoneum into this shape. This strong argument seems less tenable since more recent studies show that 10 per cent of adult males have patent peritoneal processes already formed into a sac

Other surgeons claim that every oblique hernia is congenital implying that the potential sac is in itself a hernia. Others state that the sudden appearance of a hernia must be accompanied by evidence of the rupture of tissues. No such evidence is found even in early operation on an ordinary oblique hernia nor is it necessary to adduce this evidence if the secular theory of oblique hernia is accepted.

Degrees of Involvement in Hernia—

Reducible hernia disappears when the patient lies down or when light pressure is applied.

Irreducible hernia by reason of adhesions or bulk of contents is not uncommon in very large and old hernias. An irreducible hernia may become inflamed when the omental content has been subjected to trauma by a truss or taxis with or without infection from the intestinal tract. Occasionally fecal impaction in a large irreducible hernia in an aged person causes the hernia to become choked or obstructed. The term incarcerated hernia is of vague significance being used by some as synonymous with irreducible and by certain German writers as including also strangulated hernia.

Strangulated Hernia—A hernia is said to be strangulated when by reason of sudden accession of contents and tightness of the ring or neck interference with the circulation of blood develops. If a loop of bowel is present symptoms of intestinal obstruction appear and the intestine rapidly becomes gangrenous. According to statistics on hospital admissions over 25 per cent of femoral hernias and 15 per cent of umbilical hernias are strangulated whereas only 2 to 3 per cent of inguinal hernias are found to be strangulated. Most of the strangulated inguinal hernias are oblique because direct hernias seldom become irreducible. Whether a hernia is merely temporarily irreducible, obstructed or inflamed may be of academic interest but the only safe rule must be that any hernia which suddenly becomes larger, irreducible, tense and tender accompanied by local and abdominal pain followed by nausea or vomiting is to be considered a strangulated hernia and demands immediate operation. Venous congestion and edema occur, serum collects and the intestine becomes dull red. Hemorrhagic inflammation

follows with emigration of bacteria from the intestine and bloody serum is produced and the intestine becomes purple. The serosa loses its gloss and is rough with fibrin. Gangrene seldom occurs before twenty-four hours although it has been reported as early as from four to six hours perhaps due to harmful taxis or to faulty history. When gangrenous the intestine is black or gray, lusterless, fibby, non-resilient and granular and the sac contains bloody or purulent foul smelling fluid.

Treatment of Strangulated Hernia—

Taxis should be avoided. The patient should be treated for shock and dehydration with saline or Hartmann's solution given as intravenous infusions and external heat. Gastric lavage is instituted so as to rid the stomach of toxic fluids and to prevent drowning under general anesthesia. Local or spinal anesthesia is preferable to a general anesthesia in advanced cases. Operation should run at the quickest and least shock, relief of the obstruction. After the sac has been exposed it is carefully opened. The constricted area is located with a finger in the sac and is divided by dissection from without inward, not by blind cutting from within out with the old-fashioned herniotome or history.

Cases of doubtful viability require experience and sound judgment. Even though the bowel is blue, purple or black, if it retains its luster and elasticity and shows any return toward normal color after the application of warm saline pads for from five to ten minutes it may be considered viable. At the Mayo Clinic the anesthetist momentarily administers pure oxygen which causes an immediate improvement in the color of the bowel if its circulation is intact. If resection is absolutely indicated the operation is carried out through a laparotomy incision and is wisely accompanied by an enterostomy at a higher level for temporary drainage of the paralytic ileus which persists above the point of previous obstruction. Many lives have been saved by simply leaving the loop of bowel outside the abdomen wrapped in saline gauze and using it for drainage or in less advanced cases watching it for twenty-four hours when its circulation may have so far recovered that it may be replaced within the abdominal cavity and the hernia

repaired. Immediate resection is attended by a very high mortality.

SEWARD ERONIAN

INGUINAL HERNIA

Examinations of drafted men during the first World War showed that over 2 per cent had inguinal hernias. Four fifths of all hernias are inguinal. Over 90 per cent of hernias in males and about half of the hernias in females are inguinal. The two great classes of inguinal hernia are (a) *oblique* or *indirect inguinal* and (b) *direct inguinal* hernia. A third class is the *direct indirect hernia* with its *saddle bag* or *pantaloon sac* which straddles the deep epigastric vessels and presents the combination of a direct sac together with an indirect sac both clinically and surgically this type is merely another form of direct hernia and must be treated as such. When inguinal hernias are bilateral they are practically always of the same type on the two sides.

An omental hernia or epiplocele contains only omentum. If a loop of bowel is included the hernia is called an enterocoele. When only a portion of the wall of the bowel is caught in the hernia ring it is called a partial enterocoele or Richter's or Littre's hernia. This latter occurs rarely in oblique hernia but not infrequently in femoral hernia and may progress to gangrene and perforation without complete obstruction of the lumen of the bowel. Hernia of the urinary bladder is frequently associated with direct inguinal hernia and large oblique inguinal hernias whereas sliding hernia of the sigmoid flexure or cecum is of comparatively rare occurrence and is always associated with oblique hernia.

Oblique Inguinal Hernia—In an inguinal hernia if the neck of the sac issues laterally to the deep epigastric vessel, through the internal abdominal ring and follows intimately the course of the spermatic cord it is called an oblique or indirect inguinal hernia.

Oblique inguinal hernia is ten times more frequent in the male than in the female obviously owing to the descent of the testes, and as this descent occurs later on the right side there is a preponderance of right sided

oblique hernias. Oblique hernia becomes bilateral sooner or later in 25 per cent of cases. Keith states that 44 per cent of male infants have a hernia in the first year of life but Bull found that fully two thirds of these disappear either spontaneously or with the aid of a truss. Few new hernias develop during childhood but from adolescence up to the age of thirty during the period of most strenuous exercise and physical strain the vast majority of ordinary oblique hernias make their appearance and come to operation.

Etiology—There is almost unanimous agreement today that defective closure of the processus vaginalis is the predisposing factor and that the exciting factors of suddenly increased intra-abdominal pressure and failure of Keith's inguinal shutter permit the actual development of a hernia, i. e. the protrusion of a viscus.

Anatomy—For the detailed anatomy of the inguinal region reference must be made to textbooks of anatomy and only certain points which are of importance in the surgery of hernia will be mentioned here. The spermatic cord represents the conjunct of its two major components the vas deferens and the spermatic vessels each of which approaches the internal abdominal ring from a different direction. The testis and its predecessor the patent funicular process protrudes through the internal ring between and slightly above these structures as if the cord elements furnished a slide for the sac which through it the inguinal canal lies in front of or a perfect fit to the vas and its vessels. Therefore it will be seen that an oblique sac is intimately associated with the structures of the cord and contained within the same fibrous line consisting of the funicular fascia the cremasteric fascia and the intercolumnar fascia as each of these tissues is encountered by the testis at the internal ring in the inguinal canal and at the external ring respectively.

Three arteries and three nerves are encountered in the inguinal canal namely the important spermatic artery a branch of the aorta the small artery of the vas from the internal iliac and the cremasteric from the deep epigastric. The genital branch of the genitofemoral nerve which runs beneath the cord into the scrotum the inguinal branch of the ilioinguinal nerve placed superficial to the cremaster and emerging through the external ring hence subject to injury at operation and lastly the hypogastric branch of the iliohypogastric placed still higher on the surface of the internal oblique muscle.

The inner border of the internal oblique muscle arches across the internal ring and runs almost horizontally mesally until it reaches the rectus sheath in the subumbilical line together with the lower border of the transversalis directly beneath it forms the "true muscle" border which is drawn down and sutured to

Poupart's ligament in practically all hernioplasties. The lowest fibers of insertion near the rectus sheath are described by anatomists as the "conjoined tendon" but Blake and later Bloodgood and Zieman have shown that this structure is so frequently attenuated narrowed or obliterated that its use in hernioplasty is seldom practicable therefore it is the "true muscle" border which is used and is called the conjoined muscle. The cremaster muscle is in reality merely the lowest fibers of the internal oblique muscle which originally lay across the face of the internal ring and which was stretched and thinned out as it was pushed ahead of the testicle in its descent. The deep epigastric artery arises from the external iliac near the middle of Poupart's ligament and runs upward in the properitoneal tissues directed toward the umbilicus. It forms the dividing line between the internal ring and Hesselbach's triangle.

An hernia occurring mesial to this artery is called direct whereas an oblique hernia emerges through the internal ring which is lateral to the deep epigastric.

The fibers of the external oblique aponeurosis run downward and inward toward their insertion in the pubic bone but diverge as they approach the pubis forming the pillars of the external abdominal ring. Ordinarily this ring will not admit the fingertip although about 3 per cent of male adults have a larger or relaxed ring which predisposes to the later occurrence of direct hernia.

Varieties of Oblique Inguinal Hernia—1 Ordinary oblique inguinal hernia formerly called the adult or the acquired type, is in no essential different from the hernia into the funicular process. It may reach down to the tunica vaginalis but does not communicate with it.

2 Hernia into the tunica vaginalis is preferable to the term congenital hernia, formerly used to describe complete patency of the processus vaginalis permitting the hernial contents to enter the tunica vaginalis in the scrotum.

3 *Encysted hernia and infantile hernia* Moscovitz regards as practically identical. When the vaginal process is sealed off in the inguinal canal but open below this level the oblique sac may either invaginate into the tunica vaginalis or pass down behind it thus either two or three layers of peritoneum must be incised before the hernial content is exposed.

4 *Oblique inguinal hernia in the female* occurs when the canal of Nuck remains patent after it has been dragged out into the inguinal canal by the round ligament. At operation the delicate sac is more difficult of dissection from the round ligament than from the cord in the male but this dissection should always be attempted. Some surgeons include the round ligament with the neck of the sac in the transfixion ligation and excise the distal portion others suture the stump to the margin of the internal ring in order to support the uterus and to prevent retraction of the cut ligament away from the sac ligature.

5 *Hernia with non descended testis* is very common as a part of the arrested development.

6 *Interstitial hernia* is a rare and interesting accompaniment of maldevelopment of the testis where the hernial sac unable to pass out of the inguinal canal spreads out between the muscle planes of the abdominal wall

in an upward direction toward the umbilicus. Usually the sac lies between the aponeurosis and the internal oblique but may occur in the preperitoneal space.

Direct Inguinal Hernia—A direct inguinal hernia bulges through the floor of Hesselbach's triangle formed by the floor of the deep epigastric artery, Poupart's ligament and the border of rectus muscle either separating or pushing the transversalis fascia ahead of it. Etiologically, anatomically and surgically it differs essentially from an oblique hernia.

Practically unknown in the female and in children, it occurs almost entirely in male adults from twenty five to fifty years of age. Some of the factors which weaken the defenses of the floor of Hesselbach's triangle are an enlarged external ring which is found almost exclusively in the male in atrophy or obliteration of the conjoined tendon in abnormally high position of the true muscle border according to Polya and degenerative changes in the musculature. The lipoma theory of Cloquet and Moschcowitz has been mentioned. Direct indirect hernia with its "saddlebag" sac straddling the epigastric vessels occurs in about one third of the cases of direct hernia. Its characteristics and surgical treatment are essentially those of direct hernia. Care must be exercised not to overlook and fail to remove one or the other of the component sacs.

Differential Diagnosis—In males oblique hernia occurs in 75 per cent of inguinal hernias and direct in 25 per cent. In females only 2 per cent are direct. Oblique hernia occurs from infancy up to thirty years and direct hernia usually after thirty. The oblique hernia is oval or pear shaped descends obliquely on coughing frequently is serotal and sometimes is irreducible. After reduction of an oblique hernia, finger pressure over the internal ring will prevent its recurrence whereas this is not true of direct hernias. The direct hernia is globular protrudes straight out through the external ring hardly ever enters the scrotum and is practically always reducible. The external ring is not enlarged in oblique hernia until the hernia is complete but is always enlarged in direct hernia. In oblique hernia the posterior wall of the canal feels firm when the finger is inserted in direct hernia the finger passes directly backward through the de-

fective posterior wall. The epigastric artery fails to assist in the diagnosis because it is seldom palpable by external examination.

Treatment of Inguinal Hernia.—Mechanical treatment by trusses and bandages may be curative in infancy, but such cure lacks permanency. A truss is an excellent palliative measure if disease advanced age or repeated failure of surgical cure contraindicates operation.

Injection Methods.—For a discussion of injection treatment see the paragraphs at the end of this chapter.

Surgical Treatment of Inguinal Hernia.—*Hernioplasty*, the plastic repair of the her-

nial defect by suture (Poupart's) ever results in firm union. The verdict is that satisfactory union of muscle to fascia and fascia to fascia is largely dependent on the careful removal of all intervening areolar tissue and this important fact must be remembered by the surgeon.

Modern Operations for Hernia.—All types of operation for hernia fulfill the underlying principles but differ in the plastic reconstruction.

1 *Transplantation of the Cord, the Bassini Operation.*—This operation initiated the era of modern hernioplasty and was described almost simultaneously by Marcy in

Fig. 122.—Oblique hernia. The neck of the sac is dissected away from the cord as lateral to the deep epigastric vessels and is ready for opening high transfixion ligation and excision.

nial defect has supplanted herniotomy, mere incision for the relief of strangulated hernia.

Three general principles underlie practically all inguinal hernioplasties: (a) complete dissection of the inguinal canal; (b) high ligation and excision of the sac; and (c) plastic reconstruction of the inguinal canal. Exceptions to these principles are found in the operations of LaRocque, Brucjee and Leon Sutton, who use a laparotomy incision and remove the sac intra-abdominally, a method yielding good results in their hands but which has not gained any widespread adoption. Much discussion has arisen and much animal experimentation has been pursued to determine whether or not muscle

America and Bassini in Italy. It consists of the following steps: (1) a skin incision well above and parallel with Poupart's ligament; (2) a splitting incision of the aponeurosis outward from the upper margin of the external ring; (3) a splitting of the cremaster to expose the oblique sac overlying the cord structures; (4) careful dissection of the sac away from the cord well up to the internal ring; and (5) high transfixion ligation of the sac and excision. (b) The plastic repair consists in depressing the cremaster fibers and suturing the true muscle border of the conjoined muscles down to the sliding border of Poupart's ligament while the cord is elevated out of the wound. The cord is thus transplanted somewhat outward and super-

cially, is now dropped back on the surface of the internal oblique and the aponeurosis is closed in front of the cord. If used for direct hernia the rectus sheath or the rectus muscle itself may be sutured to Poupart's ligament. Macle has advised transplantation of the cord to the femoral canal by separating Poupart's ligament and later resuturing it over the cord.

2. *Non transplantation of the cord* is typified by the Ferguson or Coley Ferguson operation and by the Johns Hopkins operation. The Bassini steps 1 through 5 are followed but for step 6 the cord is replaced beneath the cremaster; the conjoint muscles are su-

turnoplasty proceeds (a) with separate suture of the transversalis fascia and (b) suture of the conjoint muscle to Poupart's ligament (c) with the cord still elevated the upper or mesial leaf of aponeurosis is sutured to Poupart's ligament and the lower leaf is overlapped upward and sutured to the surface of the upper leaf. The cord then emerges through the aponeurosis opposite the internal ring and runs down toward the scrotum subcutaneously. The author excises the cremaster muscle to permit better closure of the inner angle and Burdick has in selected cases resorted to division of the cord which he says does not al-

tured to Poupart's ligament in front of the cord and the aponeurosis is closed.

3. *Extra-aponeurotic transplantation* was first practiced by Halsted and later modified by Andrews, Woolsey, Stetten, Downes, and Frilman. It is indicated in direct hernia and in old large obliques also in most recurrent hernias. This operation makes use of a strong fascia to fascia overlap of the aponeurotic flaps to fortify Hesselbach's triangle and its weak inner angle. In direct hernia the sac bulges through the posterior wall of the canal above the level of the cord and is never intimately related to the structures of the cord. After the cremaster is split the transversalis fascia must be opened to expose the sac. After excision of the sac the

walls cause atrophy of the testicle. Estes describes an interesting modification of the fascia to fascia operation which seems especially adapted for direct hernia. He excises the cremaster and uses a flap from the rectus sheath permitting double fascia to fascia plication to fortify the weak inner angle of Hesselbach's triangle.

Indications.—The Bassini operation has so long been the classic operation and so widely adopted that many surgeons employ it for every type of inguinal hernia. However, there are certain definite contraindications to its use: (a) In infants and young children it shortens the cord and elevates the testicle; hence it is objectionable. (b) in operations for non-descent, (c) the Bassini

transplantation operation does not adequately strengthen the inner part of Hesselbach's triangle, the area of weakness responsible for direct hernia, as is proved by the

The Ferguson non-transplantation is the operation of choice for infants and young children and in non-descent of the testis and is undoubtedly adequate for many other ob-

The distal stump of the cremaster is later tacked on the surface of the aponeurosis to support the testis.

most dependable follow-up reports, which show a recurrence rate of from 15 to 30 per cent for direct hernias treated by either the Bassini or the Ferguson operation.

lique hernias when small and without muscular or fascial defect.

For the efficient treatment of direct and direct-indirect hernia, the writer firmly be-

leaves that additional measures must be taken to fortify the weak posterior wall of the canal and to close the innermost angle where inner angle recurrence of direct hernia are so prone to occur hence the extra aponeurotic transplantation operation with excision of the cremaster is recommended for direct hernia or the Gallie fascial suture method in exceptional cases. A small direct hernia may be merely replaced.

Suture Material—Chromic catgut is most commonly used and has stood the test of time. The use of silk alone for ligations and sutures combined with meticulous handling of tissues has greatly reduced the

lies autogenous fascia. Koontz has recommended preserved ox fascia. Alloy steel wire sutures are advocated by Babcock. The silk technique method has gained many advocates recently and I believe silk is by far the best suture material for the average hernia. Recently Alton Ochsner, Gage, Harold Loss, Donald Guthrie and others have adopted the use of plain white sewing cotton as the most satisfactory form of ligature and suture superior to silk and much cheaper. As for the late results of the use of Gallie fascial sutures, Burdick's experience at the Hospital for Ruptured and Crippled in New York has been very discouraging.

Fig. 62C.—Extra aponeurotic transplant. The upper leaf of the aponeurosis is sutured to Poupart's ligament and the conjoint muscle has been sutured to the shelving barrier. The inner angle is now well closed and covered. All the lower flap is overlapped upward and sutured to the surface of the upper flap. The cord runs subcutaneously.

recurrence rate at the Presbyterian Hospital, New York (W. B. Parsons). The living fascial suture method of Gallie described in 1921 may be used for difficult inguinal and other hernias. Many years before Gallie, McArthur used a narrow fascial strip from the upper flap of the aponeurosis, but the generous supply of autogenous fascial sutures obtainable from the fascia lata of the thigh by Gallie's method greatly enlarges the usefulness of such sutures. In the Gallie operation for inguinal hernia, a special needle and technique are used to weave the fascial sutures across the hernial defect in basket work fashion, forming in reality a new fascial plane of defense. Instead of Gal-

Operative Accidents—Injury to the intestine while the sac is being opened, injury to the bladder in direct hernia and injury to the vas and to the spermatic vessels must be guarded against. Injury to the nerves may give rise to testicular neuralgia. The femoral vein should not be injured during the suturing of Poupart's ligament.

Postoperative Treatment—Rest in bed in an ordinary case of oblique hernia should be continued for eleven days, although some surgeons say eight and still others fourteen days. In cases of direct and of recurrent hernia the time should be at least fifteen days and many surgeons insist on three weeks.

Eight to ten weeks before the patient returns to work is usually allowed by labor boards but three months should elapse before any heavy work is undertaken.

Complications—Swellings of the scrotum usually temporary are the result of trauma and dissection at operation rather than lack of support of the testicle after operation they include hematomas thrombosed veins epididymo-orchitis and hydrocele. A pronounced epididymo orchitis is prone to result in atrophy of the testis later.

Recurrence—Failure to remove both components of a saddle bag sac failure to wipe away all areolar tissue too tight sutures which cut through tissues improper choice of operation too early return of the patient to work deep infection of the wound and failure to fortify the inner angle are factors in causing a recurrence. Failure to excise the cremaster is the cause of many inner angle recurrences. From a number of the largest and best surgical clinics follow up reports based on actual examinations show from 3 to 7 per cent of recurrences after operation for oblique hernia and from 15 to 30 per cent after operations for direct hernia. Probably throughout the hospitals of the country the actual rate is even higher. Over half of the recurrences are apparent within six months nearly 80 per cent have recurred within one year and about 90 per cent before the lapse of two years. Reliable follow up reports must be based only on those patients who have been followed for two years and have actually been re-examined.

Injection Treatment.—Since Ignatz Mayer of Detroit in 1927 reintroduced treatment of hernia with injections of irritants and claimed 98 per cent cures this method has gained numerous adherents in various parts of the country. Prolonged night and day wearing of a truss is an essential feature. Many types of hernia are unsuitable for injection the most favorable is the small oblique sac in a young person in a small percentage of these cases obliteration of the sac may result in a cure. The early tissue reaction causes a marked thickening which may temporarily hold back the hernia or so mark its presence that a cure is claimed for a few months.

Biopsies performed by Kelly on injected

animals at ten day intervals showed that the early fibroblastic tissue had practically disappeared in one hundred days and had been largely absorbed within fifty days. Dobson in 1940 confirmed Kelly's experiments. Coley of the Hospital for Ruptured and Crippled New York found 81.03 per cent relapses after injection treatment. The Council of the American Medical Association stated in *The Journal* on Aug 17 1940.

After due consideration of a second hospital survey [the Council] reaffirms its previous opinion that the Injection Treatment may not be recognized for general use. Universal employment of the method is to be deplored.

From reliable statistics the injection method offers a prospect of cure to one patient out of eight.

middle one for the vein and an inner channel usually filled with fatty areolar tissue which is known as the femoral canal. It is through this canal that a femoral hernia passes to enter the thigh. The upper boundary of the femoral canal is the femoral ring which is bounded anteriorly by Poupart's ligament, medially by Gimbernat's ligament, laterally by the femoral vein and posteriorly by Cooper's fascia which covers the superior surface of the horizontal ramus of the os pubis. The femoral ring is separated from the internal abdominal ring by the deep epigastric artery which lies close to the upper and outer margin of the femoral ring. When, as happens in about one third of the subjects, the obturator artery springs from the deep epigastric artery, it crosses the upper and inner portions of the femoral ring and consequently may be injured at operation if the ring must be divided. Serious hemorrhage may then ensue. The underlying density of the aponeurotic and bony structures that form the femoral ring favors early strangulation. This is also intensified by the abrupt angle made by the sac as it bulges for-

less the sac contains irreducible omentum is seldom severe. The uncomplicated case usually presents as the only symptom a dragging sensation in the groin.

Physical Examination.—On inspection a fullness, or even a distinct globular swelling may be seen, but if the patient is obese or if the hernia is small there is often no external evidence of its presence. Palpation reveals a globular mass situated just beneath Poupart's ligament and external to the spine of the pubis. Owing to the fact that the sac is frequently surrounded by considerable preperitoneal fat, the mass often fails to disappear completely when attempts at reduction are made. This does not therefore indicate the presence of irreducible omentum. A true impulse on coughing is not nearly as constant a finding as in inguinal hernia, because the neck of the sac is frequently very narrow. When strangulation is present a cramp like pain, nausea and vomiting are noted while distention may be present in varying degree. Auscultation may reveal audible peristalsis.

Diagnosis.—It should be borne in mind that the sac in some cases of femoral hernia tends to pass up over Poupart's ligament to lie above it on the surface of the external oblique and in such instances may be easily mistaken for an inguinal hernia. If the relation to the pubic spine is carefully sought for, however, it will generally be possible to avoid this error for an inguinal hernia is always internal to the pubic spine and when small is above it while the neck of the femoral sac is always external to the spine. The question can be settled with certainty, however, if the finger can be introduced into the external inguinal ring and if it is found to be empty while the swelling below persists.

ward upon the thigh after escaping from the saphenous opening. These factors tend to favor constriction and congestion of the contents of the sac. The coverings of a femoral hernia are peritoneum, preperitoneal fat (crural septum), femoral sheath, cribiform fascia, superficial fascia and skin.

Symptoms.—The patient may be quite unaware of the presence of a femoral hernia and the cramp like pain, nausea and vomiting of obstruction due to strangulation may be the first symptoms noted. It is therefore essential to include a careful palpation of the femoral area in the examination of every patient with an acute abdominal condition. Often, however, there is complaint of a painful swelling in the groin which may or may not diminish or disappear when the patient is in the recumbent position (Fig. 628). The degree of pain is variable, however, and un-

less the sac contains irreducible omentum is seldom severe. The uncomplicated case usually presents as the only symptom a dragging sensation in the groin.

Physical Examination.—On inspection a fullness, or even a distinct globular swelling may be seen, but if the patient is obese or if the hernia is small there is often no external evidence of its presence. Palpation reveals a globular mass situated just beneath Poupart's ligament and external to the spine of the pubis. Owing to the fact that the sac is frequently surrounded by considerable preperitoneal fat, the mass often fails to disappear completely when attempts at reduction are made. This does not therefore indicate the presence of irreducible omentum. A true impulse on coughing is not nearly as constant a finding as in inguinal hernia, because the neck of the sac is frequently very narrow. When strangulation is present a cramp like pain, nausea and vomiting are noted while distention may be present in varying degree. Auscultation may reveal audible peristalsis.

Diagnosis.—It should be borne in mind that the sac in some cases of femoral hernia tends to pass up over Poupart's ligament to lie above it on the surface of the external oblique and in such instances may be easily mistaken for an inguinal hernia. If the relation to the pubic spine is carefully sought for, however, it will generally be possible to avoid this error for an inguinal hernia is always internal to the pubic spine and when small is above it while the neck of the femoral sac is always external to the spine. The question can be settled with certainty, however, if the finger can be introduced into the external inguinal ring and if it is found to be empty while the swelling below persists.

Varix of the saphenous vein is a condition which may closely simulate femoral hernia. It should always be borne in mind during the examination of a suspected femoral hernia. Both conditions present a swelling in the same area which tends to disappear when the patient lies down and to reappear when he coughs or stands. The distinction must be made by the character of the sensation imparted to the finger during coughing. In femoral hernia this sensation is the peculiar crepitation which one learns to associate with hernias and which has been termed an impulse. In saphenous varix the sensation is best termed a thrill. This peculiar tactile sensation may easily

Fig. 628—Bilateral femoral hernia

Even in cases in which the contents of the sac can be completely reduced it is difficult to control the hernia completely by the most carefully fitted truss. While the bowel may be kept from entering the sac a small strand of omentum often becomes extruded and in time becomes adherent and irreducible. For this reason the writer always advises operative treatment in cases of femoral hernia in which there is no definite contraindication. In cases in which it is not deemed advisable to operate a truss should be worn to prevent the hernia from increasing in size or from becoming strangulated. When operation is refused or definitely contraindicated small reducible femoral hernias offer the best prospect of being held by a truss. Of these a cross-body frame truss with a small water-filled pad is probably the most effective and comfortable.

Operative Treatment—Two methods of approach have been recognized as standard procedures for the cure of femoral hernia: the femoral approach through Scarpa's triangle and the inguinal approach through or above the inguinal canal. While opinions differ as to which method is superior for the average case each method has its definite field of usefulness. The high or inguinal operation is particularly to be urged when strangulation is present. It is also essential when dealing with a hernia which has a large relaxed femoral ring. For by this method reduction and inspection of the strangulated contents are facilitated and resection if required is more easily and rapidly performed and where the ring is large and relaxed suturing Poupart's ligament to Cooper's ligament effectually closes the ring at its entrance instead of lower down.

Many other procedures some of them quite ingenious have been proposed but have been discarded among these may be mentioned Roux metal staple to fasten Poupart's ligament to the pubic bone, Fascia periosteum bone and muscle have been advocated in autoplasmic procedures by Silzer, Mikulicz and Edmund Andrews but for exceptional cases only.

In the average case of a small uncomplicated femoral hernia however the low approach through Scarpa's triangle gives excellent results and has the advantage of being

Treatment of Femoral Hernia—As in hernias in general the two forms of treatment to be considered are the mechanical or truss method and the surgical or so called radical cure. This latter term originated about fifty years ago when hernias were seldom operated on and treatment was almost entirely carried out by trusses. In the years that have followed the improvement in surgical technique in general and in hernia surgery in particular has placed the operative method firmly in the preferred position. This is especially true of femoral hernia because a truss virtually never effects a cure and is a more cumbersome and less effective palliative measure than is the case in inguinal hernia. Since the pad must press on the region of Scarpa's triangle it tends to be displaced with every movement. Compression of the adjacent femoral vein must be avoided. Moreover since in most cases the femoral sac cannot be completely reduced owing to the surrounding preperitoneal fat the pressure of the truss aggravates the condition and is in consequence definitely contraindicated.

more easily and quickly performed. This operation bears the same relation to femoral hernia that Bassini's does to inguinal hernia. It is recommended for general use in preference to the inguinal operation by Burdick, W. B. Coley, Seward, Erdman and Watson.

the neck of the sac the writer prefers one placed obliquely lying over Poupart's ligament. The latter facilitates the introduction of the sutures for closing the femoral ring, and should in error in diagnosis have been made the exposure of the inguinal canal is

Fig. 629.—Femoral or low operation showing the stump of the sac which has been transfixed and ligated at the neck, and a purse-string suture inserted. It when tied will close the femoral opening.

Fig. 630.—Closure using one layer of interrupted sutures that approximate Cooper's ligament and the transversalis fascia to Poupart's ligament.

Femoral Approach.—This operation with various modifications was advocated by Berger, Bassini, Cushing, W. B. Coley, Marcy and others. While the incision may be made vertical with its mid portion over

readily accomplished. The incision 3 inches (7.5 cm.) in length terminating at the pubic spine divides the skin and deep layer of the superficial fascia and exposes the sac and preperitoneal fat. These are freed from

adjacent tissues, and the neck of the sac is identified. Gentle traction and careful dissection with scissors about the femoral ring make it possible to separate the adhesions

the femoral ring can be secured, and upon this rests the success of the operation.

Next the sac is opened, great care being taken because of the possibility that though

Fig. 631.—Femoral operation for femoral hernia showing the relationship of the neck of the femoral sac to the inguinal canal and adjacent structures.

Fig. 632.—The closure of the femoral ring from above by suture of Cooper's ligament to Poupart's ligament after disposure of the sac following high ligation of the neck.*

and pull down the neck of the sac. This is the important step, for if good exposure is not obtained, neither high ligation of the neck of the sac nor satisfactory closure of

the sac seems to be empty, yet the bladder may occupy the inner wall and may be damaged. Omentum may be present in the sac

* Watson: *Hernia*, C. V. Mosby Co., Publishers.

and must be reduced if non adherent or ligated and excised. The sac together with its surrounding peritoneal fat is then ligated either separately or together (Fig 609). This is done by passing a transfixion suture well above the original neck of the sac. After it has been ligated and the sac has been excised the stump must retract well up beyond the femoral ring. This step doubtless cures the majority of small uncomplicated femoral hernias in which the neck is narrow and the femoral ring not greatly relaxed. The fascia overlying the pectineus muscle is then exposed and cleared of all areolar tissue. The sutures which are of silk or of medium chromic catgut are introduced so as to close the femoral ring. The first suture is placed innermost while a blunt retractor protects the femoral vein. It traverses Poupart's ligament and then picks up a portion of the pectineus muscle and fascia directly below the ligament the needle being directed inward away from the vein. It then passes upward to enter Poupart's ligament again about $\frac{1}{2}$ inch mesial to the beginning (Fig 630). This mattress suture is held taut and if it is insufficient to close the ring adequately a second or even a third suture may be placed before any are tied. The use of a small curved needle is important for otherwise the muscle and fascia directly beneath Poupart's ligament cannot be picked up and the femoral canal will thus be closed not at its base but at its apex. This theoretical objection to the operation is raised by proponents of the other method.

Inguinal Approach—This method was first advocated by Annandale in 1876 although priority has been erroneously given to Lotheissen who described the operation in 1898. Gordon (1900) and Moschowitz (1905) introduced modifications of the method and popularized it. During the past few decades many writers have urged that it be given preference over the femoral approach regarding it as the ideal procedure for closing the canal at the highest possible point. The incision is made as for an inguinal hernia but prolonged a trifle lower over the pubis. The external oblique aponeurosis is divided exposing the inguinal canal. The spermatic cord or the round ligament is retracted and the internal oblique and trans-

versalis muscles also. The floor of the inguinal canal is Hesslebach's triangle composed of a layer of transversalis fascia is then opened along the line of the incision and with adequate retraction the neck of the femoral sac is exposed proximal to the point where it passes into the femoral canal. Cowell has termed this the suprascapular portion of peritoneum (Fig 631). Traction on the sac if empty usually succeeds in inverting it up through the ring where it is then ligated at the point of origin. If there are irreducible contents without strangulation gentle traction combined with pressure over the femoral region below will often accomplish reduction. In some instances however it may be necessary to prolong the incision expose the femoral sac and open it below. Adherent omentum can then be ligated and excised and the sac then with drawn upward through the ring. The technique when strangulation exists will be discussed under strangulated femoral hernia.

After the neck of the sac has been ligated and the distal portion has been excised the femoral ring is closed from within by interrupted sutures. With the femoral vein carefully retracted the outermost suture is passed between Poupart's ligament and that portion of the pectineal fascia known as Cooper's ligament which covers the rimus of the pubis (Fig 630). Successive sutures are similarly placed the innermost one including Gimbernat's ligament. The transversalis fascia is then closed and the inguinal canal repaired as in an operation for inguinal hernia but without transplantation of the cord.

There is a possibility that a direct inguinal hernia may follow the inguinal operation for femoral hernia and special care should be taken in the closure of the transversalis fascia. Dickson in fact sutures the transversalis fascia to Cooper's ligament separately and then closes the femoral canal by suturing Poupart's ligament to Cooper's ligament. This modification of the inguinal method seems to minimize the danger of the development of a direct hernia subsequently due to damage to or weakness of the transversalis fascia.

Suture Material—Progressive increase in the use of non absorbable materials such as cotton or silk in repair of hernia has been

noted in many clinics. During the past six teen years of 211 operations done at Hos pital for Ruptured and Crippled in 93 en- gult and kangaroo tendon was used and in 102 fascial sutures were used but these were done prior to 1935. Since 1935 there have been 108 operations in all of which cotton, silk or nylon was used.

Treatment of Strangulated Femoral Hernia—*Taxis*—*Taxis* and operation are the only methods of treatment available. *Taxis* is a dangerous procedure attended by grave risk. It should be reserved for the rare cases in which operation would be extremely hazardous: i. e. in cases of senility and severe cardiovascular and pulmonary dis ease. Among the dangers entailed by *taxis* may be mentioned the risk of rupture or serious damage to the intestine, reduction of gangrenous intestine into the abdominal cav ity, rupture of the sac near the neck and reduction en masse with failure to relieve the symptoms of obstruction.

Taxis is absolutely contraindicated if symptoms of strangulation have been pres ent for more than one or two hours or if there are already present evidences of in flammation of the overlying skin or marked sensitiveness.

In the writer's opinion *taxis* is rarely jus tified and is usually to be condemned. A safer procedure is to place the patient in a warm bath and administer morphine hypo dermically. If spontaneous reduction does not take place within a half hour operation should be undertaken at once.

Operation—Whenever the diagnosis is clear the inguinal approach should be se lected. If when the peritoneum is opened the contents of the sac can be pulled up out of the ring the operation is not difficult and the sac can be removed after the neck has been transfixed. Closure of the femoral ring is then effected as has been previously described. If reduction is impossible by trac tion it is best to prolong the incision to expose the femoral region and the fundus of the sac which is then opened. Bimanual combined *taxis* and traction may then per mit of reduction though manual dilation of the ring or in extreme cases division of it is sometimes necessary. In dividing the ring Gimbernat's ligament is nicked an aberrant obturator artery being cautiously

avoided. Poupart's ligament should be cut only as a last resort.

When reduction has been accomplished by one means or another the contents are inspected for viability. If anastomosis is in volved it is best to resect the involved por tion going through obviously healthy tis sue. If intestine is present one must decide whether resection is necessary. If there are thrombotic areas in the mesentery or if the peritoneum has lost its gloss and the intes tine is soggy and lacking in its normal elas ticity resection is indicated. In general if the color and appearance of the strangulated segment fail to improve under the influence of warm saline pads in a ten or fifteen min ute period it is safer to assume non viability and proceed to resect.

The high operation enormously facilitates a resection and immediate anastomosis which is one reason why it is always the method of choice when strangulation is pres ent. In case an operation has been under taken through the femoral approach and the involved portion of the intestine has slipped back before its viability has been deter mined it is safer to perform a laparotomy through a lower rectus incision on the same side and examine the strangulated portion for evidence of its integrity, resecting if reasonable doubt exists.

Injection Method—Recently much has been written in favor of the injection method of treating hernia. Most writers however are aware of its dangers as applied to fem oral hernia. The proximity of the femoral vessels and the danger of damage to them at the time of injection or later due to the effect of the sclerosing solution must be ap parent. In my opinion the method is defi nitely contraindicated for this variety of hernia. As it is quite impossible to main tain at all times complete reduction of the sac by a truss it seems obvious that a cure by this means is out of the question.

Recurrent Femoral Hernia—Recurrent femoral hernia often constitutes a difficult problem because in these cases the ring is usually enlarged the structures compo ing it may have been damaged at previous op eration and the landmarks are less clearly visualized. The writer has seen the femoral vein injured in such a case with disastrous consequences. The high approach should al

ways be used for recurrent cases and use of fascial strips for sutures may be desirable.

Prognosis.—The prognosis in cases of femoral hernia must be considered first as to life and second as to cure of the hernia. It may be assumed that unless strangulation occurs life is not threatened. But this complication arises more frequently in femoral than in any of the ordinary types of hernia. According to Watson it is ten times more frequent in femoral than in inguinal hernia. When strangulation has taken place the prognosis depends on the promptness with which surgical intervention is instituted. Since women of advanced age are the most frequent subjects of strangulation it is evident that there is an added factor tending to increase the risk, i. e. the susceptibility to postoperative pulmonary and cardiovascular complications. Gibson in 1900 found a 47 per cent mortality and it is still distressingly high. Watson collected reports of 700 operations for non-strangulated femoral hernia with 9 deaths (1.25 per cent).

The prognosis for surgical cure is also dependent on the age of the patient, the size and character of the ring and its adjacent structures and the care with which the operation is performed. The earlier the condition is recognized and referred for operation the better the prospect of complete cure. Statistics furnished me by Dr. D. H. M. Gillespie covering 211 consecutive operations performed at the Hospital for Ruptured and Crippled* (New York), are as follows:

Total no. of operations	211
Recurrences	15 or 6% approx
Deaths	3 or 1.5% approx

UMBILICAL AND VENTRAL HERNIA

UMBILICAL HERNIA

Definition.—An umbilical hernia is a herniation or separation in the depression at the middle of the abdomen where the umbilical cord of the fetus was attached.

Etiology.—By many authorities all umbilical hernias are considered congenital. For the purpose of classification umbilical hernias may be divided into three forms: (1) congenital hernias due to developmental defects in the midline; (2) infantile hernias which occur soon after birth when the umbilical scar yields to straining, vomiting and coughing; and (3) adult hernias due to excessive intra-abdominal tension caused by excessive intra-abdominal fat frequently in women and occasionally in men of the laboring class. Multiple pregnancies are a definite etiological factor.

Pathology.—At birth the abdominal viscera fail to withdraw within the abdominal cavity coincident with non-closure of the abdominal ring. In some cases the sac contains part of the transverse colon, stomach, liver and rarely gallbladder. In infants and young children when there is weakness in the scar tissue that is normally closed at the umbilicus a small rounded mass protrudes through the navel. These hernias seldom strangulate are small in diameter and may disappear spontaneously because of contraction of the opening. However recurrences are likely. In adults umbilical hernia occurs more frequently in men than in women the proportion being four to one. Gradually but steadily growing larger some attain an enormous size although as a rule the ring is not large being approximately 6 or 12 cm. in diameter. The ring is generally round and well defined. I usually many adhesions are found in the sac causing the omentum, transverse colon and often loop of small bowel to become adherent at the point of focalized spaces. It is in this type of hernia that strangulation generally occurs.

Symptomatology.—Indefinite abdominal distress, dragging sensations, colicky pains, floating nausea, constipation and at times obstipation are the characteristic symptoms.

Diagnosis.—The presence of a protrusion at the navel which is partly or entirely reducible and associated in the larger form

mass with diastasis of the rectus muscles denotes an umbilical hernia. It is tympanic on percussion and if a portion of the bowel is included in the sac a gurgling sound is heard. The enlargement of the hernia when the patient is in the erect posture or on coughing and its disappearance in the recumbent position unless the contents are adherent are diagnostic evidence. The larger sacs are prone to ulceration from pressure due to clothing or some type of binder or truss intended to effect a cure. Strangulated umbilical hernias are diagnosed by the presence of a reducible mass in the sac distention of the abdomen nausea vomiting increased pulse rate elevated leukocyte count

seldom is a cure effected without operative intervention. If a hernia is allowed to progress to the stage of ulceration and perforation peritonitis will cause a fatal termination.

Treatment—In infants if the ring is small and if tight and consistent strapping with a properly fitting pad is employed a cure is effected in many instances. In adults surgical management is imperative in order to effect a cure. Proper preoperative prepara-

and rising temperature even though no strangulation exists a mild inflammatory reaction often denotes obstruction in the larger forms which may be either partial or complete.

Prognosis—If an umbilical hernia occurs in infancy it may disappear spontaneously. In adults particularly in the obese

Fig 634—Suturing of "vest over pants" completed the mattress sutures are tied and the edge of the flap is held in place by a continuous suture.

ration of the obese patient is essential particularly if there is coexistent myocardial disease or a renal disorder. Reduction in weight is necessary if the patient is to withstand operative treatment satisfactorily and if the chances of recurrence are to be minimized. The transverse or vest over pants type of repair is preferable to the so called vertical or side to side procedure. The sac should not be opened until it has been completely dissected from the surrounding structures and the surface of the fascia on either side has been well defined. When the sac is opened great care should be exercised in separating the omentum and the loops of large and of small bowel and it is necessary to clear the under surface of the anterior abdominal wall of all bowel or omental attachments for a distance of 3 or 4 inches from the edge of the true ring. The entire sac itself should be excised and only the structures surrounding the ring should be utilized for overlapping. The sac is of little use in the repair. All contents are reduced. In order to

facilitate the overlap an incision is made on either side of the ring. The mattress sutures comprise the first layer the under flap being drawn well up under the upper flap (Fig. 633 a). A most important point at this stage is the suture of the small spaces between the mattress sutures by means of interrupted carefully placed sutures (Fig. 633 b) as it is at this point particularly that recurrences are prone to occur. The edge of the overlap is then sutured at the surface of the fascia surrounding the inferior border of the ring (Fig. 634). Chrome catgut silk fascialata from the thigh and ox fascia have been the suture materials used. The anesthesia may be either local or spinal. In the case of a large hernia when difficulty is encountered in closing the ring a patch may be taken from the fascial lata of the thigh to close the defect. In every form of recurrent umbilical hernia fascia whether human or from the ox should be used. Although a longitudinal or side to side repair is occasionally used the transverse or vest over pants method results in fewer recurrences.

VENTRAL HERNIA

Any protrusion other than an umbilical hernia which occurs in the anterior lateral abdominal wall is included under the rather ambiguous term of ventral hernia. The important types in this group are: 1 *Epigastric hernias*. These are protrusions of preperitoneal fat which occur in the midline of the abdomen. Most of these occur above the umbilicus and are quite small. In many cases the patient is not aware of the hernia. Epigastric hernias are more common in men than in women. 2 *Hernias of the linea semilunaris* often resembling a lipoma appear at the outer edge of the rectus muscle and are due to developmental defects. 3 *Lumbar hernias* occur between the crest of the ilium and the costal margin. For some reason they occur more frequently on the left than on the right side. Strangulation is rare. A congenital weakness of the structures and factors that increase abdominal pressure are the cause of these hernias. They are repaired by means of fascial flaps from below the ilium and turned upward to join flaps deflected downward. Free fascial transplants are also utilized to close these defects. Operative measures have rarely proved to be

successful. 4 *Incisional or postoperative hernias* comprise the largest group of any type of ventral hernia. Hernias produced by stab wounds, crushing blows or gunshot wounds are included in this group. An incidence of 5 or 10 per cent is generally conceded in this particular type of herniation in comparison with all other types of hernia.

Etiology of Incisional Hernia—An abdominal operation particularly when drainage of a wound of the anterior abdominal wall has been instituted is an important etiological factor. Infected wounds, improper closure of a clean wound and the use of suture material of an inferior grade also are definite factors in the causation of incisional hernias. In the case of an infected wound with large sloughing areas of fascia of the external oblique or rectus sheath it is easily understood why herniation so readily follows. The smallest piece of omentum protruding through a pinpoint opening in the peritoneum either in the line of the suture or through a needle tear or slit to the side of either edge is the incipient pathologic process in a large percentage of cases of incisional hernia. The majority of these hernias start within a few weeks or months following the operation although many are not noticed for several years. There may or may not be a definite sac. The symptoms are exactly those of umbilical hernia. The diagnosis is readily made by inspection and palpation of the protrusion.

Treatment—(a) *Prophylactic*. If possible prophylactic treatment is preferable. All anterior abdominal wall wounds should be sutured with the utmost care. Particularly great pains should be taken in closing securely and firmly the cut edges of the peritoneum and transversalis fascia. Drains should be left in wounds for a minimum period of time. (b) *Operative*. A reiteration of the original anatomical relationship can often be effected but if not a side to side fascial overlap or a vest over pants overlap is usually sufficient to effect a cure. In many cases the use of fascial lata transplants or sutures is indicated and there are instances particularly in the case of a very large hernia when the repair should be carried out in stages.

HENRY W. CARR

DIAPHRAGMATIC HERNIA

Definition—The term diaphragmatic hernia is commonly used to designate any condition in which there is protrusion of abdominal contents into the thoracic cavity through an abnormal opening in the diaphragm. Any true hernia has a sac as one of its component parts so that many of the conditions which are included under this term and which do not have a hernial sac would be more properly termed eviscerations or false hernias. The presence or absence of a hernial sac cannot be determined by clinical examination but only at operation.

Pathology—There are numerous classifications of diaphragmatic hernia which are based on the embryology, etiology, pathology, anatomy, the site of the opening in the diaphragm, the presence or absence of a sac, the content of the hernia and other conditions. It is difficult or impossible to make most of these classifications clinically and accordingly many of them are of little practical value. Diaphragmatic hernias are therefore usually classified in three main groups: (1) congenital, (2) acquired and (3) traumatic.

From a clinical and surgical standpoint the history of preceding injury is helpful in establishing the diagnosis and in determining the type, urgency and prognosis of operative treatment. Because of the practical clinical and surgical significance of trauma as an etiological factor, the writer has suggested the classification of diaphragmatic hernias into two main groups: *non-traumatic* and *traumatic* and has subdivided these according to the various types as follows:

Non-traumatic diaphragmatic hernias may be further divided into: (1) the congenital type due to embryological deficiency which is usually without an enclosing sac, the most common sites of occurrence being (a) through the hiatus pleuroperitonealis (foramen of Bochdalek), (b) through the dome of the diaphragm, (c) through the esophageal opening, (d) through the foramen of Morgagni and (e) through the gap left by absence of the left half of the diaphragm; and (2) the type of hernia which is acquired after birth, the sites being (a) through a point of embryological fusion of the dia-

phragm, (b) at sites named under congenital types and (c) through the esophageal hiatus in which case the hernia has an enclosing sac (Fig. 635).

Traumatic diaphragmatic hernias may be divided into: (1) hernia due to indirect injury to the diaphragm which may occur at any point including points of embryological fusion but which occurs most commonly in the dome and posterior half of the left side of the diaphragm and usually is the result of a severe crushing injury when the hernia is through the esophageal opening there is a sac and when the hernia is through the leaf of the diaphragm there usually is no sac; and (2) hernia due to direct injury to the diaphragm which may occur at any point and is usually the result of a penetrating wound e.g. from a gunshot or a knife rupture of a subdiaphragmatic abscess or empyema may also be the cause and usually there is no sac (Fig. 636).

The presence or absence of an enclosing hernial sac is of some practical clinical and surgical importance. A sac is usually not present in a congenital hernia when there has been loss of structure of the diaphragm or in a traumatic hernia due to direct or indirect injury. As has been said this is not a true hernia. Usually several abdominal viscera and a large portion of each involved organ are encased and the symptoms are very severe and urgent. In the surgical repair of these hernias preliminary pleurotomy is often advisable and intratracheal anesthesia should be used during the repair. A hernia with a limiting sac is considered a true hernia and it rarely involves more than one organ. The most common hernia of this type is the esophageal hernia in which the stomach is usually the only abdominal organ involved. The symptoms in such cases are more uniform than in others and in the operative repair the sac must either be removed entirely or its continuity with the abdominal cavity obliterated.

Since the discovery of roentgen rays an increasing number of cases of diaphragmatic hernia have been recognized during life but the incidence of this condition is probably greater than even the present records would indicate. It is of importance to both clinician and surgeon to the clinician because of its

complex symptoms and its importance in differential diagnosis and to the surgeon because surgical repair is the only type of treatment that will relieve symptoms completely.

Symptomatology—The clinical recognition of diaphragmatic hernia from the subjective symptoms alone is often very difficult. The symptoms are complex because of the various structures involved in the hernia. They depend on the amount of mechanical interference with the function of the herniated abdominal viscera, the degree of interference with the normal function of the

involved and in which the hernia is usually of the esophageal type those in the second group occur in cases in which multiple abdominal viscera are involved and in which the hernia is usually of the traumatic type.

Esophageal diaphragmatic hernias are usually congenital. The symptoms may begin at birth or at any time during life. There may be a congenital weakness in the esophageal ring and a definite hernia may later be produced by some type of injury or by increased intra-abdominal pressure. These hernias may be considered as of traumatic

Fig. 63

Fig. 63b

diaphragm and on the amount of increased pressure within the thorax which causes impairment of respiration and circulation. The symptoms produced often simulate those of other diseases of the abdomen and thorax of which the most common are cholecystitis, gastric ulcer, cardiospasm, angina pectoris, intestinal obstruction and unexplained secondary anemia.

The symptoms of diaphragmatic hernia may be divided into two main groups. Those in the first group occur in cases in which the stomach is the only abdominal organ in-

volved but they are essentially congenital in the same manner as are hernias in the inguinal region. The esophageal type of hernia produces more uniform symptoms than hernias elsewhere in the diaphragm. The symptoms are those of intermittent or progressive incarceration and obstruction of the stomach. At the onset the attacks are usually mild, they consist of epigastric distress which is projected through to the back. They come on during, or shortly after a heavy meal and are relieved by belching of gas or by vomiting. These attacks are not uncommonly con-

sidered to be due to disease of the gallbladder. As more of the stomach becomes incorporated into the hernia the attacks become more severe the pain being projected straight through to the back and to the lower left side of the thorax it is more marked to the left of the spinal column and often appears between the shoulder blades. This pain is agonizing and there is difficulty in belching of gas and vomiting because of spasm of the diaphragm and reflex cardiospasm. The spasm of the diaphragm produces hour glass deformity of the stomach which interferes with emptying of the upper loculus and causes increased intragastric pressure. The pressure of the herniated portion of the stomach on the lower part of the esophagus also interferes with belching of gas or vomiting. Spasm of the diaphragm is commonly associated with referred phrenic pain in the left shoulder which at times may be projected down the arm. The increased pressure within the thorax causes cardiac embarrassment with palpitation and tachycardia. The pressure of the lung and the interference with the motion of the diaphragm cause dyspnea. These symptoms are augmented when the patient lies down and in the more severe cases it is necessary for patients to sit up in order to breathe. The attacks may last for from a few minutes to several hours and occasionally are considered to be caused by disease of the arteries of the heart or by myocardial disease. The attacks usually are completely relieved by vomiting and often recur immediately after food is taken.

There is often an interval of weeks or months between attacks. It is probable that during the interval between attacks the stomach is not incorporated in the hernial ring and is in its normal position below the diaphragm. When the attacks become more or less constant this usually indicates that the stomach has become fixed by adhesions in the thorax. All the early symptoms of pressure are augmented during the attacks. There is loss of weight from inability to retain food and from marked restriction in diet resulting from fear of bringing on an acute attack which may be termed a food fear. The vomiting is more severe and often is of the retention type. During severe attacks of vomiting the vomitus may contain blood. If the attacks are of long standing the pa-

tient not uncommonly has a burning sensation in the epigastrium which comes on after meals and is relieved by taking small quantities of food. If large amounts of food are taken it may bring on one of the attacks associated with incarceration of the stomach due to hernia. Often patients obtain partial relief when placed on a diet for ulcer because of the restricted amount of food taken at frequent intervals. Hemorrhage is not a common symptom but it is usually indicative of severe incarceration with fixation of the stomach in the thorax. Bleeding is caused by erosion of the mucous membrane due to the pressure exerted during the attacks of vomiting on the large distorted congested and fixed stomach. This erosion may be superficial or in cases of long standing may form a definite ulceration due to repeated trauma. This is usually the final stage of incarceration.

The symptoms of congenital types of diaphragmatic hernia due to structural deficiency in the formation of the diaphragm usually involve multiple abdominal viscera and are often similar to those noted in association with the traumatic types of hernia as there is rarely a confinement and the herniated abdominal viscera are in direct contact with the thoracic viscera. The symptoms in these cases are often more severe than those noted in cases of traumatic hernia. Because of the occurrence of the hernia at birth the respiratory and cardiac symptoms are usually the most severe owing to the marked unilateral alteration in intrathoracic pressure and the occurrence of this derangement of intrathoracic pressure at a time in which the compensatory respiratory and cardiac reserve has not been developed to a sufficient degree to maintain function of these organs. Many infants born with these congenital defects die in the first few hours or days of life. However if the respiratory and cardiac mechanisms are able to compensate for the presence of these abdominal viscera in the thorax these patients may live on to childhood or even adult life without any great amount of disability or symptoms provided intestinal or gastric obstruction does not develop. There is less likelihood that obstruction will develop in these cases than in the cases of traumatic hernia because there are usually fewer ad-

hesions between the abdominal viscera and the thoracic viscera in the former cases. When the stomach is involved in these hernias it usually becomes markedly dilated and the patients often have symptoms of partial gastric obstruction. Intestinal obstruction may occur because of bands of adhesions between the omentum and loops of

obstinate constipation with accumulation of large quantities of gas in the colon or by periodic attacks of partial or complete obstruction. The sudden onset of symptoms in these cases is usually directly related to the injury; the progress of symptoms is much more rapid and the first symptom may be that of severe gastric hemorrhage or of in-

Fig. 63. The entire stomach and a large loop of colon herniated into the left thoracic cavity. The viscera are very adherent to and have collapsed the left lung. Note that the traumatic opening does not involve the phrenic nerve interruption.

bowel or because of inflammatory bowel conditions or appendicitis.

The symptoms in cases of traumatic hernia in which the stomach alone is involved are practically the same as those in esophageal hernias, although in most cases of traumatic hernia the colon is involved and there are the added symptoms caused by interference with its function. This may be indicated by

intestinal obstruction. The respiratory symptoms are usually more marked because of the greater amount of viscera contained in the thorax; these viscera are in direct contact with the lung and pericardium, as there is no hernial sac.

Treatment.—In cases of esophageal diaphragmatic hernia in which only the stomach is involved and in which the symptoms

are mild the treatment may be conservative. In those cases in which progressively more severe symptoms are present the possibility of serious complications is very great, and all of them should be considered surgical cases unless radical operation is contraindicated.

to the diaphragm and structures within the thorax.

In all cases in which the colon or small bowel is involved in the hernia early operation is imperative because of the danger of intestinal obstruction (Fig. 637). These cases

Fig. 638—The technique of operative closure of the paraesophageal type of diaphragmatic hernia. *a* The oblique left rectus incision. *b* Exposure of the enlarged esophageal hiatus after the left coronary ligament of the liver has been cut. Approximately half the stomach has herniated through the opening. *c* Removal of the peritoneal sac from its attachment to the stomach after the latter has been replaced into the abdomen. *d* Method of closure of the enlarged esophageal hiatus by overlapping the margins of the opening. The tissues are stabilized with linen sutures; the closure is strengthened with living sutures of fascia lata and the esophagus is fixed to the margins of the closed opening with catgut suture.

icated because of the patient's general condition. Surgical treatment should be instituted before severe incarceration with obstruction and traumatic lesions of the stomach have occurred. The operative risk is increased by gastric retention and the technical difficulties are enhanced by fixation of the stomach

are usually traumatic in origin and it is best to delay operation until the acute symptoms have subsided if the patient's condition will permit.

Preliminary paralysis of the diaphragm produced by phrenicotomy is often of value in incarcerated and strangulated hernias be-

cause it prevents spasm of the muscle and relaxes the hernial ring. It is of great advantage in closing a large hernial opening when there is considerable loss of structure of the diaphragm as the relaxation of the muscle permits this defect to be closed without tension and in cases in which the diaphragm has been torn from the wall of the thorax it may be resutured to the intercostal muscles. It is also of value in cases in which there is congenital shortening of the esophagus because the relaxation and elevation of the muscle of the diaphragm following this procedure permit the hernial opening to be sutured around the lower part of the esophagus entirely above the herniated portion of the stomach. It is not necessary however in the small type of hernia in which approximation can be accomplished without undue tension. In some instances in which it seems advisable to reestablish the function of the diaphragm the nerve may be cut and sutured and function will be reestablished within from three to six months.

Phrenicotomy may be used as a palliative measure when the radical operative procedure of closure of the defect in the diaphragm is contraindicated because of the patient's condition. The rationale of this procedure is to prevent spasm of the diaphragm which is the cause of the severe attacks of incarceration of the stomach. The procedure does not completely relieve the symptoms there is always a moderate amount of gastric distress immediately or shortly after a heavy meal but the patient gets along fairly well on a restricted diet. Phrenicotomy completely relieves the acute attacks of incarceration if the stomach is not fixed in the thorax. It is not applicable to a hernia in which a large portion of the stomach is in the thorax causing marked pressure on the heart and lungs nor is it applicable in any case in which the intestines are involved in the hernia.

The only operative procedure which will assure complete relief of symptoms is replacement of the herniated abdominal viscera and repair of the abdominal opening in the diaphragm (Fig 638). The writer prefers the abdominal approach because there is little risk of thoracic complications. The thoracic approach gives excellent exposure and is preferred by some surgeons. In cases in which the abdominal viscera are adherent

to structures in the thorax these adhesions can be separated through the hernial ring with little danger of injury to the abdominal or thoracic viscera as the definite relationship of the herniated structures can be established. The presence of associated lesions in the herniated abdominal viscera can be determined as well as of any other pathologic lesion within the abdomen and there is no deformity following operation.

The postoperative care is of great importance in all cases but it is of particular importance in those cases in which there has been marked pulmonary collapse over a long period. In such cases there may be some delay in expansion of the lung following operation because of adhesions produced by the continuous collapse. There is often some difficulty at the time of operation in obtaining immediate expansion of the lung although every effort is made to expand the lung by positive pressure apparatus and also by suction of the air from the pleural cavity before the diaphragm is completely closed. In some of these cases the lung remains collapsed because of pneumothorax as the result of positive pressure which swings the mediastinum to the opposite side and embarrasses the heart. In these cases air must be aspirated immediately from the thoracic cavity following which the mediastinum returns to its normal position and the symptoms disappear rapidly. All of these patients are often greatly benefited by being placed in an oxygen chamber immediately after operation and in those cases in which there has been serious pulmonary collapse this may be a life-saving procedure. Pleural effusion in the side of the thorax on which operation has been performed is not uncommon. The fluid may absorb without aspiration or it may require repeated aspirations.

STUART W. HARRINGTON

UNUSUAL HERNIAS

INTERNAL HERNIA

(Retroperitoneal and Intraperitoneal Hernias)

Definition and Classification—An internal hernia is a protrusion or extension of a sac of peritoneum containing intra abdominal contents through a normal or abnormal

aperture or structure and is confined within the abdominal cavity. Of the many classifications, that of Steinké is the most simple and comprehensive: I. Retroperitoneal: A. Paradnodal: (1) right, (2) left, (3) duodenojejunal B. Paracecal: (1) ileocecal (superior or inferior), (2) retrocecal, (3) ileocolic. C. Inter-sigmoid. D. *Foramen of Winslow. II. *Anomalous openings: A

through which the small intestine migrates to become retroperitoneal. The intestine pushes a sac of peritoneum ahead of it.

Andrews and Papez have presented good evidence that these hernias are congenital anomalies produced during the second stage of intestinal rotation. If, during rotation, the umbilical midgut loop is oriented in a reverse direction, it is possible for the small

Fig. 639.—Retroperitoneal paradnodal hernia (after Wangensteen)

Through the mesentery. B. Through the omentum. C. Through or into the broad ligament.

Incidence, Etiology and Pathology.—Internal hernias are rare. A comprehensive but inexhaustive review of the literature revealed the following totals of reported cases, paradnodal, 248; paracecal (excluding adhesive bands), 18; foramen of Winslow, 35; anomalous openings, 39.

There prevail two very different opinions relative to the origin of the retroperitoneal hernias. Trietz and Moynihan postulated that the normal paradnodal, paracecal and sigmoid fossae or abnormal ones, due to failure of fusion during the third stage of intestinal rotation, develop into apertures

* Not a true hernia: absence of peritoneal sac

intestine to become incarcerated in its own mesentery or that of the large bowel.

In these cases the entire small intestine or a large portion of it is found imprisoned in a sac which is retroperitoneal. It may occupy a central position in the abdomen with the large bowel in its normal location (Fig. 639), or it may occupy the right half of the abdomen with the entire large bowel on the left side. The mesenteric vessels are disposed or stretched tightly about the aperture.

In a hernia of the foramen of Winslow, either small or large intestine, usually the colon, is found protruding through the foramen into the lesser peritoneal cavity.

On rare occasions a loop of bowel has herniated through an abnormal aperture in the broad ligament, in the great omentum or in

the various mesenteries. These apertures are either anomalous defects or result from disease from trauma (penetrating or non penetrating wounds) or from surgical procedure.

Symptoms—Many of these hernias have been reported as incidental findings at operation and routine postmortem examination and in these cases it may be assumed that they gave rise to few or no symptoms. In most of the other cases in which the diagnosis was confirmed at operation or necropsy there were typical signs and symptoms of intestinal obstruction usually with strangulation. A few patients had indefinite pain and dyspepsia others had symptoms of intermittent or chronic partial obstruction.

Diagnosis—Seldom has an internal hernia been recognized preoperatively, but as pointed out by Case this should be possible in many instances with the aid of special roentgenographic studies. The usual diagnosis has been intestinal obstruction cause undetermined. The mass of distended bowel has been mistaken for a cystic tumor. In the absence of symptoms of obstruction many intra abdominal lesions may be simulated.

Prognosis—Unless these hernias become obstructed they do not influence normal life expectancy. Obstructed paraduodenal and foramen of Winslow hernias usually terminate fatally. In the other types the mortality is approximately 30 per cent.

Treatment—If reducible the hernia should be reduced and the fossa or aperture obliterated. If strangulation necrosis has occurred the necrotic segment of bowel should be resected or if the patient is a high risk simply exteriorized with an anastomosis to restore continuity of the intestine at a subsequent operation. Unfortunately it is seldom possible to reduce a paraduodenal hernia or hernia through the foramen of Winslow and the situation is hopeless. Failure results from inability to enlarge the ring sufficiently to release the bowel because the ring contains such indispensable structures as the mesenteric vessels in the former group and the hepatic artery portal vein vena cava and common bile duct in the latter.

PFLVIC HERNIA

OBTURATOR HERNIA

(Subpubic Hernia Thyroidal Hernia Hernia through the Foramen Ovale)

Definition—As indicated by its name this hernia protrudes through the obturator foramen into the thigh.

Etiology and Pathology—It is the most common of the rare hernias with more than 400 cases on record. Most of the patients were women over sixty years of age. The sex ratio was 6 women to 1 man, the difference being attributed to pregnancies and the larger foramina in women.

The obturator foramen is occluded by the obturator membranes and muscles except for three small openings through which the obturator vessels and nerves pass. The hernial sac may leave the pelvis through any one of these foramina passing downward for ward and medially to appear under the edge of the pubic bone. The sac is usually located between the obturator externus, the pectineus and the adductor muscles in the lower portion of Scarpa's triangle. It usually contains small intestine rarely large bowel or tubes and ovaries. Strangulation is a common complication and was present in the majority of the reported cases.

Signs and Symptoms—There are two groups of symptoms those attributable to the constriction of the bowel and those resulting from pressure upon the obturator nerve. In the former group there are vague reflex gastrointestinal manifestations but no characteristic symptoms until obstruction takes place. There follow then the usual symptoms of obstruction and often also those of strangulation.

Pressure on the obturator nerve gives rise to a rather typical syndrome known as the Howship Romberg syndrome. It is manifested by tingling a burning sensation numbness or pain along the anterior mesial aspect of the thigh and around the knee joint. Straining and coughing increase the pain.

Occasionally micturition is difficult and frequent. These symptoms may appear with the onset of obstruction and strangulation, or if previously present, they are increased in intensity with the onset of obstruction. To relax the muscles around the obstructed bowel, the patient holds the leg in slight flexion, adduction and internal rotation.

Usually it is impossible to palpate the hernia in the thigh, but occasionally there is an obvious swelling and a palpable mass on the inner aspect of the thigh below and medial to the femoral canal or in Scarpa's triangle. It is always possible to feel the neck of the

A considerable reduction could be effected by earlier diagnosis and surgical intervention.

Treatment.—Manual reduction of these hernias is impossible, and because strangulation is probably inevitable, surgical intervention is urgently indicated whenever the condition is diagnosed. The hernia can be dealt with by an approach through either the thigh or the abdomen or a combination of the two. The abdominal approach is the more satisfactory. The ring is more accessible for enlargement, and reduction can be accomplished by traction on the bowel while

Fig 610—Obturator hernia *

sac by vaginal or rectal examination. This examination is a decisive factor in making a diagnosis and is another example of its importance as a routine procedure.

Diagnosis.—An accurate preoperative diagnosis has been made in less than one fifth of the reported cases. It has been mistaken for femoral hernia, adenitis, psoas abscess, varicose veins, phlebitis and disense of the hip joint.

Prognosis.—As a result of the high incidence of strangulation and the unskilled handling of these hernias, the mortality has been very high, approximately 75 per cent.

pressure is exerted upon the thigh. Resection, when necessary, is accomplished more readily within the abdomen.

To expose the sac in the thigh a longitudinal incision is made in the medial portion of Scarpa's triangle, the pectineus muscle is exposed and retracted laterally or divided and the adductor longus muscle is retracted medially. This exposes the sac, which, with its contents, is dealt with as in the case of a femoral hernia. Similarly, after excision of the sac the foramen is obliterated to prevent a recurrence of the hernia.

PERINEAL HERNIA

In this type of hernia there is a protrusion of intra abdominal contents through the pelvic floor into the perineum. The sac dissects downward between the rectum and the neck of the bladder, prostate and urethra in the male and between the rectum and vagina in the female.

Most of the hernias occur in women and are of two types anterior vaginal and posterior rectal. When small the anterior hernia protrudes into the labia majora. The larger ones compress the vagina laterally and extend backward to the edge of the anus. The hernia can be traced by palpation along the vaginal wall to its point of origin in the pelvis and in this way an accurate diagnosis can be made.

Because these hernias are rare they are not suspected and are mistaken for the labial form of inguinal hernias and vaginal cysts, fibromas and lipomas. A few strangulated hernias have been treated as acute inflammatory lesions by incision and with disastrous results.

The posterior or rectal type emerges behind the transverse perineal muscle and compresses the rectum in bulge into the ischio-rectal fossa. A strangulated hernia of this type may be mistaken for an ischio-rectal abscess and incision for drainage is followed by a fecal fistula or peritonitis.

Failure to recognize these two types of hernia has resulted in several surgical catastrophes. It is possible to reduce these hernias through a posterior colpotomy and to close the hernial aperture by approximating the utero-sacral ligaments or by a modified perineorrhaphy. The intra abdominal approach is preferable because it affords a more adequate exposure for a safer reduction and a more secure repair of the pelvic floor. It is the only approach through which a non reducible and strangulated hernia can be handled.

The author has observed a third type of perineal hernia which occasionally occurs following resection of the rectum. The hernia

dissects through the space formerly occupied by the rectum. In one case the hernial sac bulged through the unhealed perineal wound and prevented healing until it was reduced and the skin sutured over it. The hernia in the other case caused a large bulge of the healed perineal wound.

SCIATIC HERNIA

This type of hernia protrudes from the pelvis into the thigh through the small or great sciatic foramen. The sac usually contains the intestine or omentum or both and occasionally the bladder or an ovary. As the hernia emerges into the thigh it passes either above or below the piriformis muscle to occupy the space under the gluteus maximus muscle. These hernias may be classified as the superior and inferior gluteal types, the former dissecting along the superior gluteal artery and the latter in the periarterial space of the inferior gluteal artery.

Sciatic hernias are probably the rarest of the rare hernias. Less than 50 cases are on record and most of these have been reported as incidental necropsy findings.

From this fact it would appear that most of these hernias give rise to few or no symptoms and that their presence is unrecognized during life. Pressure on the sciatic nerve may produce pain along the distribution of this nerve. A few cases have been reported in which there was a tender swelling in the gluteal region, the swelling enlarged with straining and transmitted an impulse with coughing. Furthermore the swelling was readily reducible and apparently strangulation seldom occurred.

In the event that an accurate preoperative diagnosis is made, these hernias are best dealt with through an intra abdominal exposure. The contents of the sac are returned to the abdomen, the sac resected and the foramen closed by utilizing the neighboring fascia and piriformis muscle. The operation can be carried out satisfactorily also through an incision extending from the posterior spine of the ilium to the border of the greater trochanter of the femur. Division of the gluteus maximus muscle exposes the sac.

LUMBAR HERNIA

(Hernia Dorsalis, Petit or Grynfelt Hernia)

These hernias appear in the lumbar region and may be divided into two general groups—congenital and acquired. The required type may develop spontaneously or may follow trauma. The traumatic group is composed principally of postoperative or incisional herniations and most of these fol-

and the anterior border of the latissimus dorsi posteriorly. The superior space is less well defined and opinions vary regarding its boundaries. For the purpose of this presentation it may be said that it is bounded by the twelfth rib superiorly, the erector spinae muscles medially and the superior edge of the internal oblique laterally.

Most lumbar hernias have a large neck and give rise to no symptoms. There is as a rule, an easily reducible mass which transmits an impulse on coughing. A few patients complain of reflex gastrointestinal symptoms or a vague dragging sensation in

Fig. 681—Types of sciotic hernia.*

low an operation upon the kidney. Occasion- ally a hernia develops in a large defect in the lumbar wall from a penetrating wound and infection. Lumbar hernias occur mainly in men and twice as often on the left as on the right side.

The congenital and spontaneously acquired hernias are rare. They protrude through two spaces, the inferior and the superior lumbar. The inferior one is known as Petit's triangle, which is located subcutaneously and is bounded by the posterior border of the external oblique muscle anteriorly, the crest of the ilium inferiorly

the Min. Incarceration or strangulation is rare only 18 cases having been reported.

The differential diagnosis involves consideration of lipoma, fibroma, primary or metastatic malignant neoplasms, cold abscesses and paralytic scoliosis.

In most cases no treatment is required. An abdominal supporter or corset may relieve vague discomfort and prevent the hernia from enlarging. Operative treatment is indicated for the rare hernia which is large, strangulated or the cause of much distress. It consists of disposing of the sac if

*Lason: Hernia. The Blakiston Co. Publishers.

present and repair of the defect in the lumbar wall. This may be accomplished by approximating the edges of the muscle and fascia or may necessitate the reflecting of a pedicle flap of fascia to cover the defect. Such a flap may be fashioned from the lumbar fascia or the fascia lata covering the gluteal muscles.

SLIDING HERNIA

(*Hernie engluissade*)

Definition—This type of hernia is characterized by a sac composed only partially of parietal peritoneum. A portion and occasionally all of the sac is made up of large bowel or bladder which protrudes through the ring. The retroperitoneal surface of the organ presents as the exterior surface of the sac in the inguinal canal.

The terms sliding and landslide have been applied to these hernias upon the assumption that the large bowel or bladder slides with the peritoneum from the retroperitoneal fat and areolar tissue to which it is very loosely attached and is dragged by the peritoneum through the ring. As contributing factors it has been suggested that the bowel following rotation becomes fused to the parietal peritoneum at or near the internal ring or that it is dragged down to the ring with descent of the testicle. Brown believes that there is no sliding mechanism involved. He contends that in the beginning these hernias are ordinary ones with a complete sac and that subsequently inflammatory adhesions develop between the bowel and the peritoneum of the sac thus eliminating a portion of the sac.

Many hernias of the large bowel and bladder are not sliding hernias but like small bowel and omentum these organs merely descend into an ordinary complete sac and constitute no part of the sac.

Incidence—Sliding hernias are uncommon. Statistical reports vary widely but they probably constitute less than 3 per cent of all hernias. Unquestionably the bladder is present in the wall of a direct hernia

more often than is suspected because it is customary merely to push back the sac without opening it or determining its contents. Sliding hernias occur almost exclusively in men and usually in elderly men.

Pathology—A sliding hernia of the bladder is found principally in a direct sac only occasionally in an indirect one. The normal wall or a diverticulum of the bladder moves laterally and presents in the pubic end of the inguinal canal where it is covered only by retroperitoneal fat.

Sliding hernias of the large bowel are almost exclusively of the indirect type. They occur about equally on the two sides and always through a very large dilated internal ring. The ring usually extends down to the pubis and occupies the entire floor of the inguinal canal. On the right side the sac contains the ascending colon and cecum and on the left the descending colon or sigmoid. Occasionally the right colon is found in the left inguinal canal.

Bilateral sliding hernias are not rare. The writer has encountered 3 cases. Rare instances of sliding femoral hernias have been reported.

Symptoms—There are no characteristic symptoms unless it be the occasional occurrence of dysuria in herniations of the bladder. The symptoms are those common to hernias in general and the diagnosis is seldom made prior to operation. As a rule these hernias cannot be retained satisfactorily with a truss.

Owing to the large size of the ring strangulation seldom occurs. Occasionally appendicitis, diverticulitis or a tumor develops in the bowel within the sac.

Treatment—Sliding hernias and their operative management have received too little consideration in surgical instruction. Although uncommon these hernias are very important because they present to the unsuspecting uninformed surgeon a very perplexing problem fraught with grave hazard. The custom in many teaching clinics to delegate the operative management of hernias to the relatively inexperienced members of the staff and interns has resulted in some unfortunate disasters.

Unless the character of these hernias is recognized early in the course of the operation the bowel or bladder may be opened

accidentally in the attempt to isolate or open the sac. Also in the course of dissection the circulation of the bowel may be injured. These accidents are likely to result in disaster from flooding the operative field with urine or feces or may necessitate resection of a segment of bowel to prevent gangrene from disruption of its blood supply. The surgeon is warned that he is approaching the retroperitoneal surface of the bladder or bowel first by encountering a densely lobulated and fibrous type of fat quite different from the loose fat of the inguinal canal. With further dissection he encounters profuse venous bleeding from the rich plexus of veins on the surface of the bladder or exposes the mesenteric vessels of the bowel. Further warning is given by encountering the unmistakable muscular wall of the bladder or bowel. Since a sliding hernia of the bladder occurs mainly in a direct bulge there is seldom need for opening or exploring the sac. Should the bladder however be accidentally opened it should be closed immediately with two rows of sutures, the wound drained and the bladder kept empty for one week with constant urethral catheter drainage. In case the bowel is accidentally opened no attempt should be made to repair the hernia and the bowel should not be returned to the peritoneal cavity following simple closure unless some type of decompression is provided. It is safer to leave the bowel wall exteriorized from the peritoneal cavity in the wound with or without a catheter in the bowel.

For hernias of the indirect type several plastic operations have been devised such

as those described by Hotchkiss and Lenormant. In addition to repairing the hernial canal these operations attempt to fix the bowel at some distance above the internal ring by plication or by extensive mobilization and fixation. In the opinion of most surgeons there is little to be gained from these more extensive operations. It is only necessary to mobilize the bowel sufficiently to make possible its return down to the internal ring. The inguinal canal is then repaired by one of the several methods used for the repair of inguinal hernia. The writer prefers an operation which he described for the repair of direct inguinal hernias. This operation utilizes a strip of pectineus fascia and muscle as a deep bulwark in addition to a modified Bassini type of repair utilizing a strip of external oblique fascia as a living suture as described by McArthur. Duncan has recommended division of the cord so as to permit complete closure and elimination of the internal ring. He states that atrophy of the testicle does not necessarily follow.

The incidence of recurrence is fairly high regardless of the type of operation used. Records show a recurrence rate of 10 to 40 per cent.

XXXIV. THE GENITOURINARY TRACT

THE ANATOMY AND PHYSIOLOGY OF THE GENITOURINARY TRACT

The kidneys are situated opposite the lower thoracic and lumbar portion of the vertebral column. Each kidney weighs from 125 to 170 Gm., those in females being slightly smaller. Anteriorly the kidneys are in contact with the abdominal viscera such as the spleen, pancreas, colon and stomach. These relations are important in trauma to the kidney as the overlying structures are sometimes involved.

The kidneys are not held in place by any distinct ligaments or special folds of peritoneum but for fixation depend to a large extent on the pressure and counterpressure of the neighboring structures and on their connection with the renal fascia. The kidneys are

Fig. 612—Diagram showing relationships of kidneys, ureters and bladder.

enveloped and supported by a layer of connective tissue derived from the extraperitoneal areolar tissue which in many cases contains abundant yellow fat. This fascia has an anterior and posterior layer and is closed above and laterally but is open below and medially. Hence most displacements of the kidney are medial and downward.

For anatomical consideration the kidney can be divided into two parts: the glandular and the collecting portions which consist of the parenchyma and the pelvis and calices respectively. The glandular or functional unit of the kidney consists of a glomerulus and its tubule. These tubules drain the urine into the renal pelvis which is a thin walled expansion of the upper part of the ureter. At the hilus of the kidney the pelvis lies posterior to the renal vessels. This is helpful in

determining whether an excised specimen is the right or left kidney.

The renal arteries come from the aorta and the renal veins drain into the vena cava. The renal nerves come from the three lower thoracic and the lumbar segments of the spinal cord. The kidney has no lymphatics.

The ureter is a hollow muscular tube which carries the urine from the renal pelvis to the bladder, its average length is about 25 cm. and it is retroperitoneal throughout its length. The ureteral lumen is about 4 or 5 mm. in diameter. It is narrower at its origin at the termination in the bladder and at the junction of its abdominal and pelvic portions. It is at these points that stones traversing the ureter become lodged. A 2 mm. catheter is usually employed for catheterization. The ureter enters the bladder wall obliquely. The intramural portion of the ureter is about 2 cm. long. In the male the spermatic vessels and ductus deferens cross obliquely in front of the ureter near its junction with the bladder. In the female the ureter passes forward at the base of the broad ligament and forms the posterior and inferior boundaries of the ovarian fossa and is found 1.5 cm. lateral to the supravaginal cervix uteri. The ureter passes below the broad ligaments ("water flows under the bridge").

The bladder is a hollow muscular viscus which serves as a reservoir. When empty it lies almost entirely in the pelvis; when distended it rests in the abdominal cavity behind the rectus muscles and may reach as high as the umbilicus. The bladder is long and narrow in the infant and when filled extends relatively higher into the abdominal cavity. The average capacity is about 0.5 liter in the adult; its capacity is said to be slightly greater in the female. The top of the bladder is connected with the umbilicus by a fibrous cord, the remnant of the urachus which may be the site of tumors or cysts of embryonic origin. The neck or outlet of the bladder is continuous with the urethra and in the male is surrounded by the prostate gland.

The nerve supply of the bladder comes from two sources: the sacral segments supplying the pelvic nerves and the upper lumbar segments supplying the hypogastric fibers. The arteries to the bladder are from the internal iliac and the middle hemorrhoidal artery. The lymphatics accompany the veins and terminate in the hypogastric nodes.

The Male Reproductive Organs.—The two testes are suspended in a fibromuscular sac, the scrotum. Within the scrotum they are enveloped in a serous sac, the tunica vaginalis which contains a small amount of fluid. When this fluid is excessive it is known as a vaginal hydrocele. Each testis weighs about 20 Gm. and is composed of a tubular parenchyma which contains the seminiferous tubules and the collecting tubules which enter the epididymis (Fig. 613). The testis in embryonic life is an abdominal organ held in position

by the gubernaculum testis by which it is attached to the bottom of the scrotum. In its descent it passes through the inguinal canal, being preceded by a pouch of the peritoneum. The secretion of the testicle is conveyed to the seminal vesicles by the vas deferens, from which the secretion empties during orgasm into the posterior urethra by way of the ejaculatory ducts.

The seminal vesicles are two finger-like diverticulated sacs which serve as reservoirs for the semen and are situated between the bladder and rectum. The vesicles can occasionally be palpated with the gloved finger in the rectum.

The penis is composed of three rod-like segments firmly united together by a sheath of fascia and skin. Of these three erectile segments the corpus spongiosum is traversed by the urethra which at its distal end expands to form the glans penis. The glans is separated from the body of the penis by a constriction, the coronal sulcus. On the ventral surface of this sulcus the frenulum contains vessels of some size which may bleed profusely during circumcision or from rupture due to trauma.

Couper's glands (bulbourethral) are two pea-sized organs which lie in the membranous urethra. They secrete a thin alkaline fluid and are frequently infected in gonorrhea and may be the site of abscess formation.

The male urethra is about 20 cm long and is lined with laminated epithelium. The course of the urethra resembles the letter S but a straight instrument can be passed from the tip of the penis into the bladder. The external meatus varies in size and sometimes must be enlarged for the passage of sounds. On the dorsal wall of the urethra there are many small simple and compound mucous glands (glands of Littre) which are also found in the membranous and prostatic urethra. These glands are almost always infected in gonorrhea.

Physiology of the Genitourinary Tract—The kidney has a number of known functions and it is not improbable that it has some functions still unknown. The most widely known and similar function is that of the formation of the urine. It serves to eliminate waste products of nitrogenous nature as well as excessive water and salts. The kidney in some instances elim-

Fig 613—*a* Diagram of anatomy of the testicle and epididymis *b* diagram of anatomy of urinary bladder and external genitalia in the male

The prostate is a glandular structure which encircles the neck of the bladder and is perforated by the proximal end of the urethra. It is comparable to a chestnut in size and dimension, its apex pointing downward and its base lying under and against the trigone of the bladder. It weighs about 25 Gm. With the finger in the rectum the posterior surface can be palpated. In addition to glandular tissue, the organ contains an external layer of unstriated muscle which extends between the glands forming a stroma. The portion of the prostate in front of the urethra is almost entirely muscular and contains some striated fibers which form the external sphincter of the bladder. Unstriated fibers embrace the vesical orifice and prevent the backflow of semen during intercourse. The glands are of a branched tubular type and open through about 15 or 20 orifices into the posterior urethra. In addition there are true glands in a number of simple follicles in the anterior wall of the urethra. Because of the location of the prostate disturbances of the organ cause dysuria and dysfunction of the bladder.

inates foreign products which have been introduced into the body. Under average conditions all the glomeruli do not receive blood or function continuously but appear to work intermittently depending on the demands of the body. The administration of caffeine causes many of the glomeruli to become filled with blood and thereby causes diuresis. The rate of the blood flow through the kidney markedly influences the formation of the urine. Constriction or passive congestion of the renal vessels decreases or prevents the production of urine. Clamping of the kidney pedicle for longer than thirty minutes definitely injures the kidney causing anuria and permanently scarring the parenchyma. When there is a block of the ureter the kidney will secrete until the pressure rises to 80 mm. of mercury. At night the circulation is diminished and the amount of urine formed is less than that formed during the day, usually at night the amount does not exceed 450 cc. When the amount equals or exceeds that excreted during the day, it is an indication of renal impairment or cardiovascular disease. The kidney has

a normal output of about 30 Gm of urea but this will vary with the daily nitrogen intake. The kidney has the ability to put out either highly concentrated urine or very dilute urine. When an extreme amount of water is drunk the specific gravity of the urine may be as low as 1.001 and if water is withheld or excessively eliminated by other avenues of the body the concentration may be as high as 1.030. When the kidney fails to have the ability to concentrate and dilute the urine promptly it is evidence of renal disease. The intravenous injection of saline solution causes a diuresis which tends to reestablish the normal balance between the blood and the tissues. If salt or Ringer's solution is given by mouth or rectum so that it passes through the intestinal mucosa and liver for some unknown reason it is retained in the body to a greater extent than when given parenterally. Digitalis when indicated for cardiac decompensation causes diuresis by improving the circulation through the kidney. Mercurial diuretics act primarily on the kidneys it is thought that they prevent reabsorption in the tubules. If there is an excess of fluid lost through other channels of the body such as by vomiting, perspiration, diarrhea, etc., the volume of urine will be decreased.

Nerves pass to the kidney and so far as is known they are entirely vasomotor since there is no evidence that the kidney receives secretory nerves. There occurs in man a condition known as emotional diuresis or glycosuria and an emotional albuminuria which may be due to nervous or hormonal stimuli. Urinary flow is thought to be influenced by certain visceral reflexes. These reflexes are not so difficult to demonstrate in experimental animals. Ureteral trauma in the dog causes a reflex anuria. Clinical cases have been reported in which injury or disease in one kidney has reflexly caused the other kidney to cease functioning. Certain skeletal stimuli such as electrical stimulation of the sciatic nerve will cause a marked change in the volume of the kidney and will increase or decrease the urinary flow. The application of heat or cold to the body surface likewise influences the renal function, cold decreasing the formation of urine and heat increasing the urinary flow. Postoperative anuria may be due to the combination of a number of factors such as reflex vasoconstriction, congestion and inadequate cardiac function and dehydration, pre-existing disease of the kidneys or heart may predispose to anuria.

In the estimation of renal function many tests have been devised the details of which are to be found in manuals on laboratory diagnosis.

The urine which collects in the pelvis of the kidney, is periodically discharged down the ureter. The flow down the ureter is facilitated by peristaltic waves which occur at a rate of from three to five per minute. The rate depends usually on the urinary outflow. The ureter will function adequately when all extrinsic nerves have been removed probably owing to the fact that it contains ganglionic cells and an intrinsic plexus. An injury or stricture involving more than two thirds of the urethral circumference will inhibit the passage of a peristaltic wave and the portions above and below the site of injury retain their power of peristalsis but owing to lack of synchronization between the two segments dilatation of the upper segments occurs. Afferent nerve fibers from the ureter go

to the renal plexus and thence to the spinal centers. The passage of blood clots or clumped cellular debris through the ureter gives rise to pain. Distention of the ureter also gives rise to pain as does the passage of catheters in some instances. When a stone is impacted in the ureter preventing the outflow of urine from the kidney severe pain results. Usually the passage of a catheter above the obstructing stone causes cessation of the pain. A valve-like mechanism at the ureterovesical junction prevents the backflow of urine from the bladder up the ureters. In certain types of obstructive uropathy and occasionally even in normal persons a vesicoureteral reflux occurs. This is more likely to obtain in children. The control of the ureterovesical sphincter appears to be inherent in the musculature of the ureter and bladder.

The bladder as it gradually fills contracts rhythmically, and these contractions become greater in amplitude as the filling continues. When the capacity of the bladder is reached a contraction results in the "call to urinate" which, if responded to results in a sustained contraction and the opening of the vesical sphincters. If the "call to urinate" is not responded to the threshold of the bladder is set at a higher tension level. Infants as a rule void after the first stimulus reaches the spinal reflex centers. In the adult these spinal centers are entirely under control or influence of the cerebral cortex. After the higher centers have gained control the spinal centers although stimulated, are not released to act until the higher centers withdraw their inhibitory influence. When children are being taught voluntary control they may void during sleep. This means that the higher inhibitory mechanism has not yet gained complete control over the lower centers, as is manifest in the adult.

The loss of function of either one of the sphincters does not result in incontinence of urine; the function of both sphincters must be lost before incontinence ensues. In the so-called cord bladder which is often seen in spinal syphilis the bladder loses its sensitivity so that impulses to empty the bladder are not received and overdistention occurs. Some of the urine is forced out of the bladder from time to time causing a paradoxical incontinence—an incontinence with a full bladder. A true incontinence is said to be present when the bladder ceases to act as a reservoir, owing to paralysis of the sphincters and the urine passes into the urethra without disturbing the bladder.

The main functions of the testes are three in number: the formation of sperm for procreation; the development of the accessory sex organs and the development of the secondary sexual characteristics of the male. The latter functions are maintained by an internal secretion called androgen.

The loss of the testes before puberty results in a condition of eunuchoidism which may be either of two types: one in which the bony skeleton is elongated and the person thin and tall; the other in which the person is usually short and stout. The prostate and seminal vesicles and the penis are infantile forming no secretion. When the testes are lost after puberty the subject attains an adult-eunuch appearance. This is not as characteristic as in the puberty castrate. Most castrates have an abnormal distribution of fat about the hips; they lack hair on the face or the recte

may change slightly. The accessory sex organs atrophy, and no secretion is elaborated. The sex urge however may be present or absent. This manifestation in some instances has been retained several years after castration. In those mammals which have scrotal testes there is occasionally a retention of one or both of the testes in the abdomen. This condition is known as cryptorchidism. When both testes fail to acquire a scrotal position sterility results. Ordinarily an undescended testicle contains Sertoli's cells but few if any germinal cells. Replacement of the testes into the scrotum in most instances is followed by the recovery of the spermatogenic function. Operations for cryptorchidism should be performed before the onset of puberty. The scrotal sac serves as a thermoregulator and produces a localized environment cooler by several degrees than other parts of the body. The testes require such a temperature for the production of germinal cells.

The internal secretion of the testicles controls the growth of the accessory sex glands and secondary sexual characteristics. The maturation and descent of the testicles are dependent on the anterior lobe of the hypophysis. Administration of hypophyseal extract does not seem to affect the amount of testicular secretion in a normal animal. There is no evidence that a testicular hormone is stored in the body, immediately after castration involuntary changes occur in the accessory sex organs. The testicular hormone stimulates the growth of male accessory sex organs but has no effect on the testicle or the elaboration of the testicular hormone. Gonadal hormones of either sex exert a depressing effect on the anterior lobe of the hypophysis.

UROLOGIC DIAGNOSIS

Plan of Diagnostic Study.—The first suspicion of involvement of the urinary tract is usually obtained from symptoms, past or present, and from a routine examination of the urine. Hence a *complete history* must always be obtained with detailed information as to pain and urinary irregularities. From this knowledge alone may be obtained clear indications of the region probably involved and even of the nature

of the trouble. Next in order follows a careful and *complete physical examination*, including inspection and palpation of the external genitals, a rectal examination, a vaginal examination in women, a neurological investigation especially for lesions of the spinal cord and urine analysis. Finally come the *special examinations*—instrumental and roentgen examinations, renal function tests and determination of the chemical constituents of the blood. Emphasis is placed on the necessity for completeness of the examination up to the special investigations. Some enthusiasts stress the desirability of following through with certain of these special tests as a routine in all cases. While it is true that such a procedure will occasionally disclose unsuspected abnormalities, common sense and experience in urology will decide when the probabilities of enlightenment will warrant the additional expense, discomfort and risk to the patient, since all instrumental examinations of the urinary tract involve risks, notably through the possibility of introducing new infections or stirring up latent ones.

Significance of Symptoms.—A *chill* or *fever* indicates probable infection. *Unilateral pain in the back* or *abdomen* may signify that the kidney or ureter is concerned. *Sharp pain* in these regions, especially when radiating to the bladder or testicles (ureteral colic), points to ureteral obstruction—most commonly calculus. *Dull pain across the lower portion of the back* may have its origin in the prostate or seminal vesicles. *Suprapubic pain* is frequently due to bladder or intestinal lesions, pain felt in the groins, testicles or perineum often originates in the genital organs. *Frequency of urination* is the most common symptom caused by disorders of the urinary tract and the most deserving of careful study. First a distinction must be made between frequent passage of small amounts of urine and frequent passage of large amounts (polyuria). The latter places the ailment in the "medical" category—diabetes, certain types of nephritis, ingestion of much fluid, emotional or neurological disorders, etc. Frequent urination of small amounts, however, is of concern to the surgeon. When the frequency is diurnal only, it points to an irritation about the trigone, bladder neck, the urethra

in women or the prostatic urethra in men this may be due to a stone or tumor but most commonly is a simple inflammation. When the frequency is noted both day and night it sometimes denotes a lesion of the spinal cord rarely a true contracted bladder and commonly a physiologically small bladder—there may be obstruction to the bladder outflow (usually in the prostate but sometimes due to urethral stricture) acute inflammation of the prostate or bladder tuberculosis of the kidney and ureter or some irritating substance medicinal or otherwise in the urine. In men over fifty prostatic obstruction is considered first while in young men tuberculosis or acute prostatic infection especially gonorrhea is suspected. *Burning or pain throughout urination* originates in the urethra pain only at the end of the act indicates a lesion at or near the outlet of the bladder. *Difficulty in starting the urinary flow* may be merely a nervous phenomenon or it may be due to an overfilled bladder or to an obstruction—most commonly prostatic a *small stream or dribbling* occurs most often with prostatic obstruction urethral stricture and neurological disorders. *Initial bleeding* originates in the urethra. *Terminal hematuria* points to the bladder outlet or prostatic urethra. *Blood noted throughout the whole act of urination* may come from the kidneys ureters bladder or prostatic urethra.

Collection of Urine—Before the findings of urine analysis are interpreted it is of prime importance to know when and how the specimen was obtained. A freshly voided specimen is vastly more valuable than one that has stood chiefly because shreds may break up bacteria multiply red blood cells disintegrate and crystal and amorphous deposits form in old urine. If possible in examining urine in a surgical case a freshly voided specimen should always be used. It is a good plan to have the patient urinate successively in at least two glasses better three. The first specimen contains bladder urine plus the washings from the urethra if the urethra has been thus well irrigated the second glass contains bladder urine with rarely a cloud due to spermatozoa squeezed from the ejaculatory ducts by the muscular effort required to stop the flow of urine while changing from the first to the second

glass the third glass offers about as satisfactory a sample of bladder urine as one obtained by catheterization. Obviously the first glass will contain all the abnormalities of urine found in the bladder plus those gathered from the urethra (this specimen may be cloudy with pus due entirely to urethritis) while abnormal elements in the last glass most probably come from the kidney ureter or bladder but may have passed to the bladder from the posterior urethra because normally the internal urinary sphincter does not hold as tightly as the external. Neglect of such simple precautions too often leads to stupid deductions.

Urine Examination—While the first examination must always be complete interest largely centers on the albumin test and especially on the microscopic findings. Albumin may be found with pus from any source but is always present with appreciable amounts of blood. Pus from a kidney is apt to be associated with a more marked test for albumin than a similar amount of pus originating lower in the urinary tract. Pus casts (not frequently found) indicate a renal origin of pus otherwise the microscopic picture affords no clue to the source of either blood or pus. A few microscopists claim to be able to tell the origin of epithelial cells found in the urine but no experienced urologist should be influenced by such judgments in determining the source of accompanying pus or red blood cells.

Physical Examination—The urinary system must be regarded as merely a part of the complex body and its investigation conducted in that spirit. A thorough general physical examination should be made of every patient. Some disorder of the cardiovascular or pulmonary system (notably tuberculosis) or a lesion of the gastrointestinal tract may suggest the correct solution of a urinary problem. Moreover specific disease of other organs and the general condition of the patient are important factors influencing one's advice concerning the therapy to be applied to the urologic disorders discovered.

Particular attention is paid to the abdominal and genital organs. Enlarged or tender kidneys tenderness or masses over the ureter or bladder or a palpable or percuss

sible bladder will direct somewhat the later steps. Never must the digital examination of rectal mucosa, prostate, seminal vesicles and bladder be neglected and expressed secretion from the prostate should be routinely subjected to the microscope. Cancer, hypertrophy or infection of the prostate may readily account for blood or pus in the urine and for the symptoms.

Minor Urologic Examinations—Most patients with urinary disturbances particularly with frequency and especially in men past middle life should have the test for residual urine. After the patient has voluntarily urinated as much as he can, a sterilized catheter is passed gently to the bladder under aseptic conditions and any remaining urine is collected and measured. If residual urine is found, this is one of the most trustworthy evidences of prostatic obstruction but may indicate a diverticulum or deficient bladder function due to neurological disorders. Before the catheter is withdrawn the bladder capacity is measured by introducing a bland sterile solution. If a catheter will not pass or a stricture is otherwise suspected, exploration of the urethra may be done at this stage with sounds and bougie à boule and possibly filiforms. The silken bougie à boule affords the most reliable means of diagnosing stricture—by feeling the constriction as the bulbous swelling at the end of the staff jumps by.

A roentgenogram is made if there is any indication of calculus and some surgeons include this simple painless procedure as part of a general routine. The roentgenographic exposures must always include the entire urinary tract. Often stones are found in unsuspected regions; they may be symptomless but are potentially if not actually harmful. About 90 per cent of all urinary stones are of such chemical constitution that they can be demonstrated roentgenographically. If further special examinations are contemplated, these simple roentgenograms should be made first as their disclosures will influence the subsequent procedures. The possibilities of diagnostic exploration with the urologist's special instrumentation are so great that all of them cannot be employed routinely. The maximum discomfort to the patient attends this part of the investigation; hence the wis-

dom of gathering all the other relevant information first so that the greatest aid may be obtained from one special instrumental examination.

Urethroscopy and Cystoscopy—In the use of the following and indeed of all urethral instruments the utmost gentleness and regard for aseptic surgical technique are required.

The instruments used for the final localization and determination of obscure urinary diseases are possessed of visual and lighting properties and may roughly be grouped as *urethroscopes* (or endoscopes) and *cystoscopes* designed for inspection of the urethra and bladder respectively. The light is usually derived from a small electric bulb placed at the end which first enters the urethra or bladder. Vision is accomplished sometimes through an open tube but usually through a system of lenses arranged similarly to those in a microscope. Urethroscopes permit direct examination (and treatment) of the walls of the urethra; the detection of inflammatory lesions, stones, papillomas, etc. Their usefulness is particularly important in the diagnosis of lesions of the posterior urethra such as abnormalities of the verumontanum obstructing inclusions or prostatic lobes and sinuses from a ruptured abscess.

But the cystoscope opens up possibilities of diagnosis and treatment not only of lesions of the bladder but also those of the ureter and kidney. Modern cystoscopes consist of an outer sheath usually bearing the lighting system, a well fitted obturator used only during the passage of the sheath and interchangeable telescopes for use within the sheath. These may be for observation only, commonly at right angles to the long axis or this space may be given over only in part to the visual system allowing room for the passage of one larger or two smaller catheters, bougies, electrodes, forceps or other operative devices to be used under visual control.

By this means one may inspect the bladder mucosa, noting inflammations, general or localized ulcers, tumors and calculi; diverticuli or general trabeculations; the vesical outlet is studied for evidences of prostatic irregularities and protrusions from the normal contour; the trigone is carefully noted for

hypertrophy (due usually to great effort to open the sphincter muscle in the presence of certain types of prostatic obstruction) ulcers tubercles or neoplasms. The ureteral orifices demand especial attention—their size and shape whether they function normally whether the ejected fluid is clear cloudy or bloody whether indeed there are more than two openings. After the intra-venous injection of certain dyes commonly indigocarmine one may gain important knowledge of the relative value of the kidneys by noting the time of appearance of the color at each orifice and the ultimate relative density of this color (meritoscropy or chromoscropy). But the most valuable information concerning each kidney is obtained by catheterizing both ureters and obtaining synchronously urine from the two sides. These are compared microscopically noting especially pus blood or bacteria and are examined for the amounts or percentages of any excretory product (usually urea) from the two kidneys. At the same time bacterial cultures are made directly from the urine obtained by catheters from the kidneys. The figures of urea percentages give some idea of the relative functional capacity of the two kidneys but another test is usually added for confirmation. Of the many possible ones the indigocarmine and phenolsulfonphthalein tests are commonly used the latter being preferred as it is easy to estimate the actual amount of dye excreted by each kidney in a definite period of time. (If the urea and color tests do not harmonize repetition of the cystoscopy may be necessary.) Thus it is possible to declare definitely whether one or both kidneys give signs of infection whether there is active bleeding from either (before catheters are passed) and roughly what their relative functional value is under existing conditions. But tests do not estimate the potential function of kidneys or indicate their capability under more favorable conditions. Through the ureteral catheters the capacity of the renal pelvis may be measured by injecting a bland fluid (normal saline) with little force pain may be deliberately caused in the kidneys so that the patient may voluntarily compare it in character and location with a symptomatic pain—sometimes a very valuable diagnostic aid. In normal cases

urine drops from ureteral catheters intermittently if a catheter is high enough to tap a dilated pelvis (hydronephrosis) or ureter there will be a continuous flow. If a ureteral calculus is suspected but not evident on the roentgen film it may be diagnosed by the passage up the ureter of a small catheter containing a bulb of wax near its tip this wax will probably be scratched deeply and clearly as it passes the stone. Marks made on the wax by possible contact with the cystoscope are flat and superficial. To differentiate further the catheter is rotated on withdrawal thus making the calculus scratch a spiral in form.

Roentgenography and Cystoscopy Pyelograms and Ureterograms—Still further information is obtained through the employment of cystoscopy and roentgenography combined. The location of shadows on the roentgen film near the line of the ureter may be accurately determined by taking a stereoscopic pair of films or a lateral film while a radiopaque catheter is in the ureter. A stone in the ureter will hug the catheter in films taken from all angles and in the stereoscopic pair will be clearly seen near the catheter and in the same lateral plane. Through the catheter the renal pelvis and ureter may be filled with a solution opaque to the roentgen rays and an outline of these cavities may be obtained on roentgenograms (called pyelograms and ureterograms). Of the many substances used in the development of this method sodium iodide has become universally popular it gives good outlines is cheap and is relatively non-toxic and non-irritating. But it has been found that the newer materials developed for intravenous use (noted later) are even less irritating although more expensive. Thus are demonstrated dilatations constrictions irregular cavities (representing destructive processes) and filling defects. The latter are parts of the normal pelvic or ureteral lumens which should but do not contain any of the opaque fluid and which are evidently occupied by another substance such as a stone tumor or blood clot. These films will show the exact location of renal stones already demonstrated on earlier films whether in the pelvis or calices and will sometimes indicate the smaller percentages of stones which are not visible on simple roentgen

films as filling defects. By this method characteristic visual evidence is obtained of hydronephrosis, polycystic kidneys, cysts and neoplasms, certain congenital deformities such as double pelvis and ureters, non-rotated kidney and horse shoe kidney are clearly demonstrated. Incomplete filling of the pelvis and calices may cause erroneous deductions. If air is carelessly injected a false filling defect will appear. In cases in which the outline of the kidney is not clear the exact location of the organ and its size are depicted. The mobility is determined by making exposures with the patient first reclining and then upright.

Cystograms and Uretrograms—By injecting into the bladder through a catheter a fluid opaque to roentgen rays an outline of the vesical cavity (cystogram) is obtained which shows irregularities of the contour or filling defects caused by new growths, blood clots or large stones in the bladder, pressure by masses from without, diverticula, trabeculation, local absence of distensibility (scar), etc. Similarly the urethra may be filled and its outline portrayed—this has been found useful in studying prostatic encroachment on the urethra and bladder lumen; the rare urethral diverticula and other irregularities.

Intravenous or Excretory Urograms—A great advance has been made as a result of the laboratory synthesis of compounds containing much iodine which are not too disturbing when given intravenously and which when excreted by the kidneys fill the urinary tract with a fluid opaque to the roentgen rays. Iopax and neoiofax, skiodan and neoskiodan are the trade names of materials in common use. Now good reports are made concerning other substances which may be given by mouth and are excreted by the kidney in sufficient concentration to allow satisfactory urograms to be made in many cases.

Thus the whole collecting part of the urinary tract can be outlined on a roentgenogram. The entire lumen from kidney to urethra or a part of it is outlined roentgenographically; is called a urogram. The intravenous method which gives satisfactory outlines in many cases affords also something of a test of renal function as only a relatively good kidney is capable of excreting

within five minutes the substance introduced intravenously.

The intravenous or secretory method of making urograms and the catheter or retrograde method have some values in common and each has individual advantages so that it seems that one will never entirely replace the other. Their relative values and the indications for their use clinically cannot be discussed here.

Renal Function Tests—The commonly employed methods of comparing the functional ability of the two kidneys have been briefly described but it is of much more value in most urologic work and of fundamental importance always to know the total renal function of a patient. Many tests affording some indication of this have been devised and many discarded. Only those in popular use today can be referred to here. Certain non-protein constituents of the blood are estimated most frequently the total non-protein nitrogen, urea nitrogen and creatinin; their normal values are from 30 to 40, 10 to 15, 0.5 to 1.5 mg. per 100 cc. of blood respectively; the specimen being obtained before the patient has partaken of food in the morning. Figures above those given indicate a retention of waste products and generally a corresponding renal deficiency. The urea clearance test of Van Slyke is probably the most valuable indicator of renal function but in practice most urologists feel that this method is too exacting for frequent repetition. Another group of tests depends on the ingestion or injection of various substances normally found in the body or entirely foreign and the determination of the amount of each the kidneys can excrete in a given time. Experience has shown the practical value and simplicity of such tests done with foreign substances especially dyes and the estimation of the output is simple. Phenolsulfonphthalein is pre-eminently popular. 0.6 Gm. is injected intravenously; the time of appearance is noted or arbitrarily called five minutes and collections are made during four subsequent half-hour periods. Quarter-hour periods give a more correct view but this is impracticable for various reasons. A normal pair of kidneys will excrete 50 per cent of the dye injected in the first half hour with rapidly decreasing amounts in the succeeding pe-

riods. Smaller amounts in the earlier periods with equal or larger amounts later indicate a poorer degree of function. The details of this and other renal function tests and their practical application must be sought for in larger works.

ALEXANDER R. STEVENS

CONGENITAL ANOMALIES OF THE GENITOURINARY TRACT

Congenital anomalies are fairly common in the genitourinary tract, being more frequently encountered in the urinary tract than in the genital tract. Since the urinary tract is hidden, the diagnosis of these anomalies can be made only at autopsy or at

ANOMALIES OF THE KIDNEY

For purposes of discussion the anomalies of the kidney may be grouped according to the number, form, position, structure, and blood supply. The anomalies of the ureters are closely associated with those of the kidneys.

A. Anomalies of Number—1. Bilateral absence of the kidneys is incompatible with life but has been reported (Price and Murless).

2. Unilateral absence—Complete absence of one kidney is true agenesis and is the result of complete failure of development of the ureteral bud. Associated with this condition is complete absence of the ureter and the ureteral orifice. This condition should

Fig. 644—*a*, Gross specimen (removed at operation) of a fused supernumerary kidney with complete reduction of the ureters to within 3 cm. of the bladder where they fused to form one opening into the bladder; *b*, gross specimen of polycystic kidney (removed at operation). Hematoma and marked infection made operative imperative. The patient lived for two years.

operation or by cystoscopic and roentgenographic studies. Before any surgical procedure on the urinary tract is carried out it is of utmost importance first to establish whether or not an anomalous condition is present.

Surgical correction of many of the anomalies of the genitourinary tract is not only possible but urgently desirable. Sometimes several painstaking operations may be required to correct one condition. An operation for the correction of an anomalous condition of the genital tract should be carried out when possible before the patient reaches ten years of age.

Anomalies of the urinary tract and of the genital tract are commonly associated

not be confused with a fusion anomaly in which one kidney has fused with the opposite one. In some cases in which the ureteral bud has partly developed there will be a ureteral orifice with a ureter that ends blindly but no kidney. These are not cases of true agenesis.

A single kidney is more frequently found in the male and is usually on the left side. An incidence of 1 case in 2000 autopsies is reported by various observers. Goldstein has reviewed the literature on congenital absence of one kidney. Collins recently reported an incidence of 1 in each 700 cases in a series of 6349 consecutive autopsies.

When there is complete congenital absence of one kidney there is always resul

tant compensatory hypertrophy of the other kidney with enlargement of the renal pelvis and calices. This enlargement of the pelvis and calices is not present in cases of required compensatory hypertrophy of the kidney.

A single kidney becomes of clinical importance only when it is the seat of a pathologic condition. It is subject to some type of pathologic condition in 40 or 50 per cent of

3 *Supernumerary kidney* may be unilateral or bilateral. They may be free or fused. A free supernumerary kidney is entirely free from the kidney on the same side, a normal kidney being present on the opposite side. The supernumerary kidney is usually at a lower level than the normal one and is somewhat irregular in outline as well as smaller. A free supernumerary kidney is probably the rarest of congenital anomalies.

FIG. 613.—a Pyeloureterogram of bilateral supernumerary fused kidneys with complete reduplication of the ureters. b bilateral ureteropyelogram of a horseshoe kidney verified at operation. A stone was removed from the left kidney. The calices point medially on the left but downward on the right. c bilateral ureteropyelogram of congenital crossed dystopia. There is a stone in the dystopic kidney. d cystogram of a congenital diverticulum of the bladder. The small shadow is the diverticulum. It was removed at operation.

cases. Associated with this anomaly malformations of the genital organs are found in about 75 per cent of cases. Some of the anomalies that are found are uterus bilocularis, uterus unicornis and pseudohermaphroditism. Surgical treatment of a congenital single kidney is far more hazardous than surgical treatment of a kidney when both kidneys are present. Burrell has reported a case of unilateral congenital renal agenesis with tumor.

In 1937 Geisinger found reports of 40 cases including 2 of his own.

A fused supernumerary kidney or double kidney, as it is frequently called, is more common than the free type. The bilateral occurrence of the condition is less frequent than the unilateral (Goldstein and Shaw). In this condition the upper kidney is less developed than the lower one. From its size and contour the upper kidney appears to be the supernumerary one and is frequently

rudimentary Triple kidneys are very rare but have been observed (Hanley)

A *rudimentary kidney* in itself occurs only occasionally

The anomalies just described are of extreme clinical importance particularly when operation is contemplated Supernumerary or double kidneys are frequently the site of pathologic conditions All types of renal disorders such as hydronephrosis pyelonephrosis tuberculosis calculi pyelonephritis neoplasm and polycystic degeneration of the kidney have been encountered in the supernumerary structure The diagnosis of the condition is made by cystoscopy and pyelography by either the retrograde or the intravenous method

B Anomalies of Form—1 A horseshoe kidney occurs about once in every 1000 cases In this type of anomaly the union takes place across the midline in the region of the lower poles of the kidneys and ventral to the aorta and vena cava Occasionally the union is posterior to the vessels the union may also take place in the upper poles of the kidneys The result of the common form of fusion presents a semicircular mass with two ureters and vessels coming off from the ventral or mesial aspect of the kidneys The union is known as the isthmus and consists of either connective or renal tissue According to Gutierrez the patient has a horseshoe kidney syndrome which is characterized by pain in the umbilical or epigastric region gastrointestinal disorders and intermittent attacks of urinary disturbances According to Botez in about 16 per cent of the cases the kidneys undergo pathologic changes and only then do they give rise to symptoms The type of pathologic condition found is principally hydronephrosis but calculi tuberculosis pyelonephritis and neoplasms have been described in some of the cases of horseshoe kidney (Goldstein) The diagnosis of this condition is all ways possible before operation

2 Other uncommon fusion anomalies such as disk kidney sigmoid kidney or hump kidney have been described

3 *Kidneys with Supernumerary Calices*—On rare occasions extra calices are seen entering the renal parenchyma from the outside Eisendrath collected reports of 3 cases and described a case of his own

C Anomalies of Position—A kidney that has never occupied a normal position but is lower is known as an *ectopic kidney* When an ectopic kidney is on the proper side it is said to be *dystopic* when it is on the opposite side there is said to be *crossed dystopia* The kidneys may not be fused (Beer and Ferber) The ureter usually goes to the proper side but is short because during embryonic life it did not lengthen normally and therefore the kidney did not ascend to its proper place The renal vessels arise from the nearest vessels usually the common external or internal iliac arteries Bilateral renal ectopia occurs seldom (King Morgan and Stone)

D Anomalies of Structure—1 Congenital hypertrophy has been observed in cases of congenital absence or congenital atrophy of one kidney The size and functional capacity of the normal kidney are increased The pelvis is larger and there is an increase in the number and size of the glomeruli and tubules

2 *Congenital Hypoplasia*—When the renal parenchyma of the columns of Bertin fails to develop to its full extent there is a resultant small not fully developed kidney known as a hypoplastic kidney Such a kidney is frequently predisposed to disease

3 *Aplastic Kidney*—Congenital aplastic kidney is just another name for hypoplastic kidney There may be lack of development of the kidney or degenerative changes may have taken place during its development Cysts and fetal lobulations as in an atrophic kidney are usually not observed Symptoms are present only when pathologic changes have occurred

4 *An atrophic kidney* is the remnant of an undeveloped kidney and ureter on the side opposite a congenital single kidney The diagnosis is made by means of the pyelogram and is of extreme importance clinically if surgical treatment is contemplated for the normally developed kidney The remaining parenchymal tissue usually is not normal therefore a relative functional test demonstrates a delayed appearance time and total reduction of function This is not true of a hypoplastic or aplastic kidney for which the appearance time is normal but there is demonstrated a decreased total output Cystic degeneration is usually present

5 Congenital Cystic or Polycystic Kidney—The theory of the double formation of the tubules is believed by Hildebrandt to be the cause of polycystic kidney. He believes that the cystic condition is due to the failure of union between the collecting tubules and the metanephrogenic anlage. With the beginning of the secretion of the glomerulus there is no outlet because of non union hence a cyst forms. The condition is observed about once in every 500 autopsies. With present day methods of diagnosis the condition is observed more frequently and earlier than formerly. The condition may be recognized in infants and children today because of the better means of diagnosis. The condition is usually diagnosed in patients between the fourth and fifth decades of life. There are some hereditary and familial tendencies.

A study of the urine and blood and pyelography make the diagnosis definite. The specific gravity of the urine is low and a trace of albumin and occasional blood cells are the usual findings in the urine. The low phthalein output and the high urea content are fairly constant features. The elongation of the pelvis and calices without dilatation of these structures is significant. The cause of death in over 50 per cent of the cases is uremia. It is interesting that neither medical nor surgical treatment offers a great deal of relief except in the unusual case. Removal is contraindicated except when an emergency arises such as hemorrhage or severe infection in one of the polycystic kidneys (Goldstein and Klotz) but puncture of the cysts the removal of some or the production of a cutaneous renal fistula offers some relief at times. In 4 cases in which the writer operated a temporary nephrocutaneous fistulous tract was produced on both sides and gave remarkable relief (Goldstein).

E Anomalies of Renal Vessels—Numerous reports of various dissections of series of anatomic specimens have demonstrated that in 56 per cent of the cases there is more than one renal artery and vein. As many as four separate ones have been found on each side. These accessory vessels usually enter the poles of the kidney, the upper pole being the more frequent site. The vessels originate in most instances from the aorta but may arise from other large vessels.

These anomalies in the blood supply are of considerable surgical importance particularly in the production of obstruction when the anomalous vessel crosses the ureter.

ANOMALIES OF THE URETERS

There may be complete absence of the ureters on both sides, complete absence or atrophy on one side, complete duplication on one or both sides or incomplete duplication on one or both sides. Such a condition is most frequently associated with an anomalous condition of the kidney. When an extra ureter is present with an extra pelvis it is observed that the upper portion of the pelvis is drained by the ureter which has the lower ureteral opening in the bladder. Three ureters on one side have been reported (Hanev Miller). The diagnosis is made entirely by means of the cystoscope, the ureteral catheter and roentgenograms made after an opaque solution has been either injected through a ureteral catheter or given intravenously. Bilateral complete or incomplete duplication of the ureters is the least common of all the conditions found (Goldstein and Shaw).

Occasionally an accessory ureter may be present on one side with an extra intravesical ureteral orifice but without a double pelvis. In these cases the ureter ends blindly in its upper portion (Hinman).

The ureter as well as the kidney frequently may assume an unusual position. In crossed dystopia the ureter crosses the midline. If more than one ureter is found in the lower portion usually each has a ureteral orifice of its own. The ureter may also assume a post-caval position (Shib). The ureteral orifice may be strictured or stenosed. The ureter may be small or dilated above the stricture resulting either in atrophy or a hydro-nephrotic kidney. In most cases the stricture occurs close to the bladder.

A cyst of the ureter may occur and may be the result of stricture. It may be either intravesical or extravescical. In the intravesical type a marked bulging appears in the bladder. Owing to maldevelopment the ureteral orifice frequently terminates in some organ other than the bladder (Crenshaw and Buechel) such as the vas deferens, seminal vesicle, ejaculatory duct, prostatic utricle or urethra in the male in the vestibule of the

vagina Gartner's canal uterus or fallopian tube in the female or in the rectum

ANOMALIES OF THE BLADDER

Complete absence of the bladder has been reported. *Double bladder* has been reported by Cathelin and Sempe. A septum may lie in the frontal plane dividing the bladder into an anterior and a posterior compartment or it may lie in the sagittal plane making a right and a left bladder. About 20 cases in which there were two *multilocular bladders* have been reported. These cases as well as those in which there is a septum are not cases of true double bladder. Cases of true double bladder are usually associated with a double penis or with anomalies of the penis and urethra. Cases that are reported of double bladder should not be confused with cases of diverticular bladder which may also be found as an embryological defect (See section on Diverticulum of the Bladder). Definite diagnosis of these conditions can be made by cystoscopic and roentgenographic examination.

The *urachus* which is the remains of the cord running from the apex of the bladder to the umbilicus may be patent either in full or in part. When it remains fully patent there is discharge of urine from the umbilicus. If it is only partially patent a urachal cyst may form.

A patent urachus or a urachal cyst is of clinical significance only when it causes symptoms. As a rule no symptoms are present unless the structures become infected.

Exstrophy of the bladder is fortunately a rather infrequent condition occurring about once in 30 000 cases. It is most likely the result of defective embryological development and the anterior portion of the bladder and lower portion of the abdominal wall are missing. When this particular region of the abdomen is exposed for examination the floor of the bladder the mucosa of which is thrown into many folds and its trigone are seen. In most instances the ureteral orifices can be found. In cases of complete exstrophy there is wide separation of the pelvic bones with absence of the symphysis pubis. The penis is small the urethra is epispadiac and incomplete and the scrotum is small. The verumontanum and the ejaculatory ducts are often observed on the floor of the

urethra. The prostate and seminal vesicles are either atrophic or absent. Other anomalies may be associated with this condition such as spina bifida and the presentation of an open intestinal tract on the abdomen. It occurs about eight times more frequently in males. When it is seen in the female the urethra is open from above and hypospadias is present.

ANOMALIES OF THE URETHRA

Absence of the urethra when the penis is present is rare. Reports of only 7 cases having been collected by Kaufmann. When this condition occurs it means that there was failure of the urethralanlage to develop. The production of a solid cord in place of the urethra once it has been formed is also an anomaly which has been reported.

1 Supernumerary Urethras or Urethral Canals.—In this anomaly the duplication may be partial or complete and may be situated either dorsally or ventrally. When it is partial the canal usually runs for a short distance from the external meatus being termed an accessory urethra. If the duct runs into the bladder then a true double urethra is present. An anomalous urethra may be associated with a supernumerary penis, vagina or rectum. Duphrallus or duplication of the male external genitalia in whole or part is a relatively uncommon disturbance of development. Nesbit and Bromie in a search of the literature found only 45 cases reported in a span of nearly three hundred and twenty five years. In 6 of these cases a double bladder was found but there was no demonstrable connection between the two bladders. A splitting of the vesicourethralanlage is in all probability the embryological etiologic factor as in the case of a double bladder.

2 Paraurethral Ducts.—Paraurethral ducts are not supposed to have the same embryological development as accessory urethras. They are observed around the external meatus are small and frequently are associated with other embryological defects of the penis and urethra such as hypospadias. In many instances they end blindly but in others they connect with the urethra after they have run a short course of 3 to 10 mm.

3 Congenital Obstructions of the Urethra.—Complete obliteration of the urethra

occurs rarely. The most common form of occlusion occurs at the external meatus frequently in association with phimosis. The most important type of congenital obstruction of the urethra is caused by congenital valves. These are limited to the posterior portion of the urethra usually in close relation to the verumontanum. Three types occur: (1) distal, (2) proximal and (3) superior to the verumontanum. They are comprised principally of folds of mucosa of the urethra causing urinary obstruction with subsequent dilatation of all structures behind the valves. The treatment consists principally of removal of the obstruction by dilatation or excision of the valves. David and Newberger have reported on congenital valves of the prostatic urethra and state that the number of cases reported reaches nearly 100. They describe an unusual anomaly of identical congenital valves of the prostatic urethra in twins.

4 Diverticula and Cysts of the Urethra—Diverticula are more common in the pendulous portion of the urethra. Cysts of the urethra occur as a result of the occlusion of one or the other duct of Cowper's glands.

5 Hypospadias—In this condition there is malformation of the penis and urethra. The external meatus is located at some point proximal to its normal situation but always on the ventral wall of the urethra. According to Young the meatus may be glandular, penile (Fig 646), penoscrotal, scrotal, perineal or pseudovaginal.

Hypospadias is the most frequent anomaly of the urethra. Young says the incidence is about 1 in every 160 but the writer has found it less frequently. Embryologically it is due simply to an arrest in the development of the urethra. Associated with this defect is the condition known as congenital chordee which is found principally in the severe grades of the malformation. The symptoms depend on the degree of malformation and there may be no symptoms except with regard to the direction of the stream. The sphincters of the urethra are not involved in these cases.

6 Epispadias—In this malformation the urethral orifice is found dorsal to its normal position. It may occur in either sex and is frequently associated with ectropion of the

bladder. Young divides them into the glandular penile and complete epispadias in the male and the clitoral subumbilical and complete in the female. The condition is less common than hypospadias occurring approximately once in 1000 cases. The condition is less common in the female. The sphincters of the urethra are involved causing either partial or complete incontinence of urine. On account of the abnormal curvature produced coitus is impossible.

ANOMALIES OF THE TESTIS

This organ is developed on the anteromedial surface of the Wolffian body. From the Wolffian duct the vas deferens is developed and from a small offshoot of the Wolffian

Fig 646—Hypospadias (penile type). The arrow points to the orifice. The condition was corrected by operation.

duct the seminal vesicle and ejaculatory duct are formed.

1 Anorchidism, Monorchidism, Polyorchidism and Synorchidism—Absence of a testicle is rare and is the anomaly least frequently encountered. Bilateral absence of the testicles has been reported by Counseller and Walker and by Fleet. Meyer reported in 1927 on 21 cases of absence of one testis. Cases of absence of the epididymis, the vas deferens, the seminal vesicle and the ejaculatory duct have been reported but complete absence of all four structures has never been noted. The presence of an extra testicle has been noted by Jordan and Dodson who also reported cases of other authors.

Synorchidism is a fusion of both testicles within the abdominal cavity—a rare anomaly.

Ectopia of a testicle has been reported by Campbell and by Minschat. They have encountered a testicle in the perineal position. 2 Hypertrophy and Atrophy of the Testis.—True congenital hypertrophy of a testis has been reported by Fernandez. Congenital atrophy of the testis occurs occasionally and is due to a defect of formation during fetal life.

HYDROCELE

When the cavity between the tunica vaginalis and the abdominal cavity remains open congenital hydrocele of the tunica vaginalis results. The same incomplete closure of the peritoneovaginal process may occur somewhere along the cord and then hydrocele of the cord results.

The diagnosis of hydrocele is readily made. The hydrocele of the tunica vaginalis may or may not communicate with the peritoneal cavity. In the latter event the fluid content may be forced into the peritoneal cavity by compression of the hydrocele. Noncommunicating hydrocele of the tunica vaginalis and hydrocele of the cord have a firm fluid consistency and may be transilluminated. They may grow to large size and become thick walled.

The treatment of hydrocele is surgical. Injection of irritants to obliterate the cavity has proved to be unsuccessful. Either excision of the sac wall or the 'bottle operation' is advisable. In the latter the upper part of the sac is incised and the sac is then turned inside out a few sutures anchoring it in this position. If the hydrocele communicates with the peritoneal cavity hernioplasty is necessary.

PSEUDHERMAPHRODITISM AND HERMAPHRODITISM

those of either sex. The author recently encountered a patient who came to operation a girl of 14 with hirsutism. There was a well developed penis measuring 4.5 cm in length and a well developed vagina. All the internal female organs were normal. The urethra opened into the vagina. No adrenal tumor was present nor were testes present.

UTRICLE SEMINAL VESICLE AND VAS DEFERENS

In pseudhermaphroditism anomalous conditions of the prostatic utricle are frequently found. In the male the müllerian duct which should undergo degeneration does not do so and then there may be the formation of female organs. Anomalous tube-like structures may also form from the müllerian duct and from part of the spermatic cord or a cyst along the cord. The seminal vesicle, ampulla and vas may be absent even when the testicle on the same side is present and normal. If a testicle is present with its epididymis then a vesicle and vas are usually present. The vas practically always runs to the testis of the same side.

of the kidney. In this condition the infection is originally limited to minute areas of focal suppuration in the renal cortex widely disseminated but not extending to the medulla or pelvis.

5 *Pyelonephritis perinephric abscess* and *paranephritis* describe the somewhat variable group of pathologic changes resulting from infection around the kidney but primarily external to the true renal capsule.

The above terms are both pathologic and clinical descriptions of renal disease but as is apparent from their definition may be rather loosely applied in clinical work. They frequently occur simultaneously or overlap in their extent of involvement.

Routes of Infection—Bacteria reach the kidney (and ureter and bladder) by four main routes:

A *Hematogenous* (blood borne)

B *Lymphogenous* (through the lymphatic channels)

C *Ascending* (a) Through the lumen of the ureter from the bladder below (b) along the sheath of the ureter or (c) by way of the ureteral lymphatics (as in 2)

D *By contiguous or direct suppuration*

A *Hematogenous Route*—The transfer of bacteria to the kidney through the blood stream seems most common in ordinary practice. By this route organisms are absorbed and carried to the kidney from the tonsils, apices of teeth, throat, nasal sinuses, middle ear, appendix, gallbladder, fallopian tubes, alimentary tract, endocervix and cutaneous lesions. Bacteria are not excreted by the normal kidney but only pass out in the urine as a result of an infectious lesion in the urinary tract. The kidney, contrary to past teaching, can no longer be regarded as a simple filter for bacteria carried to it from other parts of the body. One or both kidneys may become infected from a blood borne source.

B *Lymphogenous Route*—There are two possible routes by which infection through lymphatic channels can reach the kidney.

1 *From the Lymphatics of the Colon to the Perirenal Lymphatics and from These to the Kidney*—This pathway is said to infect the right kidney more frequently because of direct lymphatic distribution from the right half of the colon. Clinically it seems to be the route in some instances of renal infection secondary to ulcerative colitis and

INFECTIONS OF THE URINARY TRACT

Bacteria reach the urinary tract from some infective source in another part of the body or by ascent through the urethral lumen. Infection in the kidney, ureter and bladder is therefore always secondary to a systemic focus or to urethritis.

NON TUBERCULOUS INFECTIONS OF THE KIDNEY

Kinds of Infection—In the order of frequency of occurrence the kinds of infection are as follows:

1 *Pyelitis* (or *pyelonephritis*) implies infection in the walls of the renal pelvis, calices and portions of the parenchyma of the kidney usually limited to the pyramidal region.

2 *Pyonephrosis* implies massive infection of the renal parenchyma and calices with gross pathologic destruction of tissue. This condition is frequently the result of or accompanies obstruction to the free outflow of urine from the kidney or ureter.

3 *Infected hydronephrosis* implies pyelitis in a dilated renal pelvis and calices but without suppurative destruction of renal tissue.

4 *Cortical infection* (abscess) is sometimes called acute hematogenous infection.

acute inflammatory conditions of the bowel, such as follows ptomaine poisoning and acute dysentery. It is claimed to be the pathway in the tropics, where dysentery is so frequently followed by urinary infection.

2. *By Way of the Lymphatics of the Ureteral Wall and Peroureteral Sheath.*—This is probably an uncommon route but may carry bacteria from the male and female urethra

ureter and thence to the kidney. This is apparently the route in certain instances in which there is residual urine in the bladder and in which bacteria gain entrance through catheterization or instrumentation or following surgical operations on the bladder or its outlet. It is possibly the route in some of the renal infections in girls and in women with urethritis or gaping urethra.

SOURCES OF URINARY INFECTION

Primary foci of infection and contributing intrinsic causes and results in urinary tract.

Fig 617—Sources of urinary infection

and bladder, the female pelvic organs and the prostate and seminal vesicles to the kidney.

C. *Ascending, or Urogenous, Route.*—This presumes that the bladder has become primarily infected from below, without prior renal infection, and that the bacteria are carried up through the lumen of the ureter to the renal pelvis. This mode of infection is the result of regurgitation or reflux of a small portion of the bladder content into the

D. *Contiguous or Direct Infection.*—Infection may be carried by extension through tissues adjacent to the urinary tract, as in subphrenic abscess, diverticulitis, retrocecal appendicitis or direct perforation into the urinary tract by similar suppurative conditions.

Causative Organisms.—In non tuberculous infections of the urinary tract the common infecting organism may be either (1) bacillary or (2) coccal.

1. **BACILLARY.**—In about 70 per cent of patients

seen in general practice the organisms responsible for infections of the kidney and bladder belong to the so-called colon typhoid group. These are gram negative and may be of the hemolyzing or non hemolyzing type the latter being more common. While there have been more than 70 strains of *Bacterium coli* isolated the tendency in clinical work is to classify these in two main groups: (a) *Escherichia coli* (b) *Bacillus coli aerogenes*. This latter classification is considered important from the point of view of treatment which will be considered later.

Bacterium typhosus is the causative agent in secondary infections of the kidney and bladder occurring during typhoid fever. The comparative rarity of this disease naturally makes typhoid an increasingly uncommon

Pneumococcus infection occurs rarely. The gonococcus (gram negative) has been identified as the cause of infection of the upper urinary tract in less than 100 cases reported in all the world's literature. This latter fact is emphasized to controvert an impression among medical students and some practitioners that gonococcal infection of the kidney is a common condition.

The degree and persistence of bacterial infection in the urinary tract therefore depend on (1) the virulence and character of the infecting organisms (2) the continued activity of the primary focus of infection (3) the presence of causes in the urinary organs themselves which interfere with the normal escape of urine (obstruction or atony) and (4) the patient's resistance (factors of immunity) to the specific organisms present.

A-Normal, B-Pyelitis, C-Cortical abscesses, D-Diffuse pyelonephritis, E-Infected hydronephrosis, F-Pyonephrosis, G-Perinephric abscess

Fig. 618—Diagram showing various types of renal infections

form of urinary infection. Cases of typhoid pyelitis are occasionally reported without evidence of demonstrable infection of the intestinal tract or the gallbladder.

Bacillus proteus and allied organisms which split urea from the urine and favor precipitation of alkaline salts may be the sole invaders of the urinary tract or they may occur with the *B. coli* group.

B. pyocyaneus and other gram-negative bacilli are uncommonly present in pure culture as the cause of urinary infection.

Coccal.—Next in frequency to the colon bacillus the causative organisms in the etiology of renal and vesical infection are the gram-positive cocci. *Staphylococcus albus* and *aureus* are most common and streptococci are less common. Hemolyzing streptococci most frequently cause acute cortical infection of the kidney, a serious lesion fortunately not common. Non-hemolyzing streptococci may exist alone as the cause of renal infection but more often are associated with *Bacterium coli*.

Pathology.—It will be easier to understand the changes which take place in renal infections if they are considered as clinically acute and chronic.

Acute pyelonephritis is usually a bilateral condition but may be limited to one kidney in fulminating infections of the blood stream. In the early stages on gross inspection the entire surface of the kidney reveals the presence of innumerable minute hemorrhagic areas. On section a few areas are visible in the parenchyma, but the surface epithelium of the pelvis is densely underlaid with larger areas of hemorrhage. This local reaction may progress and at a later stage the hemorrhagic areas may be occupied by various sized soft yellow abscesses. Micro-

scopically the punctate hemorrhagic areas correspond to bacterial emboli which fill the capillary loops glomeruli or tubules. The changes in the pelvis are less marked in acute pyelonephritis than in the chronic forms. The mucosa is swollen and red with varying areas of ecchyma. There is edema and thickening of the walls of the pelvis and surrounding peripelvic and perireteral tissues. Massive localization may give rise to cortical abscesses or a carbuncle of the kidney.

B Chronic pyelonephritis shows pathological lesions of varying type and degree. The changes may predominate in the parenchyma or in the pelvis or may present in equal involvement of parenchyma and pelvis. When the parenchyma is chiefly involved there is a circumscribed or diffuse fibrosis scattered irregularly throughout the renal substance. These changes may result in atrophy of the kidney, perirenal adhesions, thickened perirenal fat, thickened rigid pelvis and ureteral walls and diffuse areas of scar tissue in the renal cortex.

When pelvic changes predominate the walls of the pelvis and calices become thickened and fibrotic with resultant dilatation and rigidity. Minute nodules of circumscribed lymphoid infiltration (granular pyelitis), minute retention cysts (pyelitis cystica) or metaplasia of the epithelial lining with skin like replacement of the epithelium (leukoplakia) may result.

When changes of equal intensity occur in the pelvis and the parenchyma (this constitutes the majority of cases of chronic pyelonephritis) there may be added to dilatation of the pelvis and its calices a compression atrophy of the parenchyma. If localized areas of destruction occur multiple cysts containing pus may be found in the renal substance (pyonephrosis).

All phases of these changes may be found depending on the severity and virulence of the infection, the presence of obstruction to the free outflow of urine and the duration of the reaction.

Clinical Picture of Pyelonephritis—In general despite age or sex the clinical picture of renal infections may best be classified as (1) *without signs or symptoms localized to the urinary tract* or (2) *with signs and symptoms pointing to the urinary tract as the source of infection*.

1 Cases without localizing signs

A Acute fulminant infection with high fever is often preceded by a chill, sudden elevation of temperature, rapid pulse, stupor and marked toxemia. There may be associated nausea, vomiting and anorexia. No frequency or disturbance in urination and no rigidity or tenderness in the lumbar region or on renal palpation is noted. There is variable although usually moderate elevation of the leukocyte count. A moderate amount of pus is found in the urine usually with a definite trace of serum or nuclealbumin and bacteria (often cocci) on urine culture. Occasionally pus may be absent from the urine in the early stages. Such a clinical picture often occurs in children and in pregnancy and the puerperium and may give rise to the erroneous diagnosis of gastroenteritis, peritonitis, influenza, typhoid, etc.

B Acute febrile reaction of less severity may be characterized by a sudden onset with or without preceding chill, moderate elevation of temperature with frequent and marked remissions but no particular evidence of stupor or toxemia. No reflex gastrointestinal symptoms are present and only slight if any leukocytosis. A moderate number of pus cells and bacteria are found in the urine. No renal or lumbar pain is felt and there is no frequency or disturbance of urination.

At the onset the diagnosis can be made only by exclusion and on the faintly suggestive urinary findings. If the urinary infection does not subside rapidly in a case belonging to group A or B localizing symptoms frequently develop after a day or two and pain in the lumbar region, frequent or painful urination and an increase in pus and bacteria in the urine suggest definitely the presence of infection in the urinary tract.

C Subacute or Chronic Pyelonephritis Without Localizing Signs Pointing to the Kidney—In this group of cases which is very large the initial symptoms are those of infection in the bladder or urethra but there are no symptoms pointing to the kidney. Bladder disturbance is the initial symptom of renal infection in 50 per cent of cases. The central symptom is frequency of urination with pain or burning during voiding. In the male urethral discharge and pain in the urethra and perineum may precede the bladder

symptoms and yet be entirely secondary to acute renal infection. Systemic symptoms in this group vary widely from febrile to afebrile and from great bladder discomfort to mild annoyance on urination.

Silent pyuria is a term given to a condition in which there is a marked amount of pus and bacteria in the urine from renal and vesical infection and yet the patient has no other local or systemic symptom of disease.

2 Cases with Localizing Signs.—*a* In acute febrile onset frequently preceded by a chill sudden elevation of temperature, weak rapid pulse and signs of acute infection plus pain in the costovertebral and lumbar region, rigidity of the erector spinae and upper abdominal muscles and an enlarged tender palpable kidney are characteristic. There is an increased leukocyte count and pus is present in variable quantity in the urine. Symptoms of bladder disturbance may or may not accompany the onset. The temperature may remain elevated or may rapidly become intermittent in type.

b Subacute or chronic type with localizing signs is usually preceded by frequent or painful urination, notable pyuria or hematuria with pain in one or both lumbar regions. The onset is not associated with noticeable chills or fever or any toxic systemic reaction. The urinary findings include albumin, pus, blood and bacteria.

Diagnosis.—All persons suffering from urinary infection may present combinations of these symptoms. A positive diagnosis is made only by finding bacteria and pus in the urine. A complete physical examination is necessary with exclusion of pulmonary or intra-abdominal lesions plus evaluation of the renal or vesical signs of infection. These must be confirmed by positive urine cultures and the findings of pus, blood and epithelial debris in the urine. One must especially consider the urinary tract as possibly infected whenever fever and other symptoms of generalized toxemia are prominent without localizing signs.

Differential Diagnosis.—Since urinary infections are secondary to infection elsewhere in the body it is well to remember that co-existing prior infection may mask or in turn be masked by the primary complaint. Appendicitis, salpingitis and pneumonia are frequently forerunners of secondary renal

infection and the proper evaluation of the severity of each condition must be made.

In general the respiratory infections such as influenza, bronchopneumonia and pneumonia must be differentiated from acute renal infection. Subacute cholangitis, enteritis, pelvic inflammatory conditions, malaria and typhoid fever must be differentiated in more obscure cases. The most important consideration in cases with localizing symptoms is the recognition of renal or perinephritic

Fig 619.—Diagram of a new method of collecting urine separately from each kidney.

abscess or renal carbuncle and the differentiation between infection alone and infection associated with renal or ureteral stone, hydronephrosis, movable kidney and pyonephrosis. The latter calls for diagnostic measures in addition to the usual complete physical examination with blood and urine tests.

Special Features of the Physical Examination in Cases of Urinary Infection.—*a* An especially careful search for possible foci of infection outside the urinary tract.

b An examination of the external genitalia. In males

the caliber of the urethral meatus and the lumen of the urethra. The possibility of residual urine in the bladder and the presence or absence of infection in the prostate and seminal vesicles must be considered. In females there should be an examination for endocervicitis, cervical erosions, salpingitis, calibration of the urethra for stricture and if there is vaginal evidence of a relaxed bladder floor (cystocele), an estimation by catheter for possible residual urine.

c. *Urinalysis and urine culture.* In the male a voided specimen is usually sufficient for proper urinalysis while in the female a catheter specimen may be necessary. Urine cultures may be obtained in the male, after careful cleansing of the glans penis, with voiding directly into a sterile container. In the female cultures must be made from urine obtained by catheterization. In addition to complete analysis special note should be made of the relative quantities of pus cells and bacteria and smears made of the urinary sediment in addition to cultural studies. These smears should be stained by the Gram method and if there is any suspicion of urinary tuberculosis by the Ziehl-Neelsen method.

Cystoscopy should be reserved until it is evident that the infection is not a transitory one which will yield quickly to medicinal treatment and elimination of obvious foci of infection. In all other cases this method of visualizing the bladder and collecting the urine separately by *ureteral catheterization* of each kidney is of the greatest importance in achieving a definite diagnosis of the source, extent and character of the infection. On cystoscopy evidence of bladder infection (cystitis) is manifest, as is the presence or absence of an obstructing prostate gland, bladder stone, diverticulum or tumor, ureterocele (cystic protrusion of the ureteral orifice), stenosis or retraction of the ureteral orifices. With a catheter collecting urine separately from each kidney, urine is obtained for analysis, bacteriologic examination or guinea pig inoculation. After intravenous injection of phenolsulfonphthalein or indigo carmine solution the appearance time of the dye from each kidney is noted and quantitative outputs over a given period of time may be recorded. These tests indicate in a relative measure the eliminative function of the kidneys. With an opaque catheter in each ureter roentgenograms may be made so as to show the course of the catheters and their relation to opaque areas if they are present on the films. The outlines of the interior of the renal pelvis, the calices and the ureters are made by injecting material opaque to roentgen rays into the catheters sufficient to fill them to a normal capacity. This procedure is called *ureteropyelography* and may be described as "retrograde" to distinguish it from the method of injecting substances into the blood stream which are eliminated in sufficient strength in the urine to demonstrate the outline of the renal pelvis and ureters in roentgenograms. The latter method is called "excretion urography."

A direct diagnosis of the nature, extent and severity of renal infection is made from a combined consideration of the clinical picture plus the information obtained by the aforementioned special diagnostic studies.

A differential diagnosis must take into consideration all of the lesions which may produce symptoms of fever, pain, gastrointestinal upset and abnormal urinary function. By utilization of modern methods, the diagnosis of disorder of the urinary tract has been raised from one of clinical speculation to a most accurate and definite objective study.

Every patient who is suffering from an infectious fever, cutaneous infection or retention of urine or who must undergo a surgical operation faces the possibility of renal infection. Prophylactic treatment embraces the prevention of infection from such sources by as free elimination as possible, avoidance of dehydration, excision and drainage of localized areas of infection, the avoidance of an overdistended bladder and extreme gentleness and careful asepsis in the passage of catheters or other instruments into the bladder.

A. Treatment of Acute Renal Infections,

—a. *Supportive treatment* includes rest in bed, proper diet, a fluid intake of 3 to 4 quarts daily (by mouth, proctoclysis, hypodermoclysis or vein as the occasion demands) and attention to proper bowel elimination, augmented by mild catharsis or enemas if necessary. Antiseptics by mouth are largely valueless in acute pyelitis, as they may upset the stomach and are exerted in too great dilution to be of value. Large doses of alkali are sometimes helpful in preventing acidosis and in reducing the edema of the urinary passages. Urinary antiseptics given intravenously are occasionally used with effect in some cases of severe renal infection. Those most frequently used are mercurial solutions (mercuurochrome, metaphen), neo-salvarsan and hexamethylenamine.

b. Cystoscopic or Surgical Treatment—

If the temperature continues to be elevated, if there are repeated chills or if the toxic symptoms are evidenced by rapid pulse, nausea, vomiting and distention, there is either retention of urine in the kidney pelvis or suppuration in the parenchyma of the kidney, and drainage either by ureteral catheter or by surgical intervention (decapsulation of the kidney, nephrotomy) is indicated. Occasionally an acute suppurating kidney must be removed (nephrectomy).

B Treatment of Chronic Renal Infection—This includes (1) drugs to change the reaction of the urine (2) urinary antiseptics (also the ketogenic diet) (3) ureteral catheterization ureteral dilation (4) dilation of the renal pelvis dilation of the urethra (5) the elimination of foci of infection in other parts of the body and (5) operative measures

1 A time honored method of administering drugs which alternately acidulate and alkalinize the urine has found favor with many practitioners especially pediatricians. This is based on the laboratory evidence that the gram negative bacilli (enteric phoid group) which are found in about 75 per cent of all cases of urinary infections are inhibited in growth when the hydrogen ion concentration of the urine is below 5.5 and above 7.5. This is merely a supportive or palliative measure and rarely in itself effects permanent sterilization of the urine. Drugs used for alkalinization include potassium citrate sodium citrate (60 or more grains daily) or sodium bicarbonate in larger doses. For acidulation the following are of value: acid sodium phosphate 60 or more grains daily ammonium chloride 40 or more grains daily and ammonium nitrate or sodium benzoate in similar dosage. Recent studies of the effects of a ketogenic diet show that dietary measures are more efficient in obtaining the lowest possible hydrogen ion concentration (greater acidity than is obtained even by a tolerance drug dosage by mouth).

2 *Use of Urinary Antiseptics*—Countless so called urinary antiseptics are made available to the profession and the public by commercial drug manufacturers. Their number suggests that none is universally or satisfactorily effective in destroying the bacteria in the urine. These drugs fall in two general classes: (a) formalin splitting and (b) dye containing. The oldest and still most helpful drug in most urinary infections is one which is composed of some derivative of hexamethylenamine and which when excreted in a definitely acid medium splits off formaldehyde in the urine. The resultant formaldehyde has an inhibiting effect on bacterial growth. The objections to the drug are the necessity for a high acidity of the urine and the possibility of causing renal irritation in

some subjects. The use of drugs which contain dye substances that are selectively excreted by the kidney presupposes the liberation of antiseptic properties in sufficient concentration to be bacteriostatic. In an occasional patient one or the other of these drugs may be very effective but in the main they are inert and expensive and frequently cause gastrointestinal irritation.

The employment of a *ketogenic diet* is a method of controlling the degree of acidity of the urine and purposely for urinary antiseptics creating a condition of mild ketoacidosis. The diet is one of excess fat free protein and only such carbohydrate as is contained in 5 per cent amount in vegetables. As a result of the proper application of this diet acetone and diacetic acid appear in the urine the acidity is reduced from pH 5.2 to pH 4.4 and beta oxybutyric acid is found in the urine. The combination of the high acidity which is unfavorable to bacterial growth and the presence of beta oxybutyric acid which is said to be bactericidal constitutes the rationale of the method. It is said by some observers that *Escherichia coli* and not *Ketogenes coli* are destroyed in ketosis. Others believe that it is effective in both types of infection. The diet is particularly easy to control in children and is most effective in pyelitis during infancy and childhood.

Mandelic acid has largely replaced the ketogenic diet. For adults 12 Gm. of mandelic acid is given daily in the form of sodium or ammonium mandelate. A smaller dose is given to children and infants. The urinary concentration must be kept high by restricting fluids to 1000 to 1200 cc. for the twenty-four hours. The pH of the urine must be kept below 5.5 by an acid ash diet or the addition of acidulating drugs such as ammonium chloride or ammonium nitrate. This regimen should not be continued longer than two or three weeks. The urine must be examined frequently for the appearance or increase of red blood cells and casts. These signs of renal irritation call for cessation of treatment with mandelic acid. In instances of renal insufficiency it may be impossible to give the drug because of the severe acidosis resulting. Contraindications to mandelic therapy other than renal insufficiency are repeated attacks of nausea vomiting and hyperper-

Calcium mandelate is a much more palatable medium for mandelic therapy than derivatives of either the sodium or the ammonium salts and its ingestion is followed by less gastrointestinal disturbance.

Sulfanilamide (prontylin) an azo dye is in some respects a most effective urinary antiseptic although the toxic reaction induced in many cases precludes its universal application. This drug is excreted in concentration in the urine dependent on the dosage by mouth. At present oral administration appears just as or more effective than the intramuscular or intravenous routes. *Sulfanilamide* is frequently effective for most of the bacterial infections and is the only drug available at present which will destroy *Bacillus proteus*. Cocci infections of the urine may or may not be eradicated by *sulfanilamide*. *Streptococcus faecalis* does not respond. This drug is active possibly more so in alkaline urine. It is therefore advisable to keep the pH at 7.5 or higher. Large quantities of fluid (3000 to 5000 cc daily) should be ingested. Bacterioid urine develops even in instances of renal insufficiency. The dosage is as yet not standardized. When the drug is given in large doses the initial quantity is usually 60 to 80 grams daily divided into four doses. After the third day the dose is reduced to 40 grams daily and from this time on gradually it is reduced to 15 grams daily for a sufficient period to insure sterile urine. If a larger dose cannot be tolerated an initial dose of 15 to 20 grams daily may be continued for two or three weeks. Since many patients do not tolerate this drug careful almost daily observation should be the rule. Many bizarre reactions occur. Progressive cyanosis, hemoglobinuria, hematuria, fever, leukopenia, agranulocytosis, erythremia, dermatitis, anemia, jaundice, muscular weakness, fatigue, and retinitis are all symptoms which contraindicate continuance of *sulfanilamide* therapy. Prompt recovery usually ensues with discontinuance of the drug. Several deaths have been reported in conjunction with this therapy but in carefully observed patients no serious results have been reported. Frequent blood counts should be made and no type of sulfate especially magnesium sulfate should be given during the administration of *sulfanilamide*. The exact manner in which sul-

famamide acts as a bacteriostatic agent is not clear. Some observers believe the essential reaction is biologic while others feel that the microorganisms are destroyed by a purely chemical action. A reasonable tenet seems to be that after the killing of the microorganisms the biochemical products of this destruction are absorbed and in the process of absorption they act as a vaccine and thus increase the resistance of the body to the infection. The fact that large doses produce a severe reaction sometimes fever when first given and fail to produce such reactions after the infection has begun to subside helps to sustain this thesis.

The improvement in the efficiency of the sulfa drugs has been so rapid that it will undoubtedly be difficult for any textbook to keep abreast of the times except by frequent re-edition. Sulfapyridine superseded *sulfanilamide* as a urinary antiseptic only to be rather quickly replaced by *sulfathiazole*. The newer drug *sulfadiazine* may replace *sulfathiazole* in the treatment of urinary infections since its ingestion seems to be followed by fewer toxic reactions. The initial dose of these latter drugs is 45 grains daily for the first two to three days and then 30 grains daily, gradually reduced to 15 grains until at least two negative urine cultures have been obtained. When these drugs are taken with milk and nicotinic acid ($\frac{1}{2}$ gram tablet) the undesirable reactions are reduced.

Experiments are proceeding along this line and a more efficient urinary antiseptic drug than is yet available may result.

Penicillin therapy is strikingly effective in certain types of coccal infection of the genitourinary tract. There is no pretherapeutic way of determining which of the infecting strains will be sensitive to this form of treatment. In general most forms of staphylococci and pneumococci are rapidly eliminated from the urine by the intravenous or intramuscular injection of penicillin. The hemolytic streptococci (especially Lancefield group A) are fortunately uncommon invaders of the urinary tract but when present in pure culture are usually eliminated by penicillin. Hemolytic streptococci other than those in group A and *Streptococcus viridans* may or may not be favorably influenced by penicillin. Infections due to

gonococci and meningococci are almost invariably eliminated rapidly by penicillin therapy. In general the dosage used in all genitourinary infections varies from 10-50 000 units intramuscularly every three to four hours. The duration of treatment is dependent on the severity and extent of the infectious process and on the rapidity of clinical response. In genitourinary infections an aggregate of 100-300 000 units of penicillin usually constitutes the minimum dose. In general if there is no clinical response in four or five days continuation of penicillin therapy is not indicated. A large percentage of urinary infections are of the mixed type *coccal* and *bacillary*. These are usually difficult to treat with penicillin and in general are relatively resistant. Occasionally alternate courses of sulfonamide and penicillin therapy will eradicate a mixed infection of the urinary tract in a surprisingly rapid manner. Unfortunately these instances are the exception and not the rule.

3 *Ureteral catheterization* effects the drainage of infected urine that is retained in the kidney pelvis and ureter. The relief of stasis and the improvement in outflow of urine following this procedure is often sufficient to allow the natural forces of immunization in the body to destroy the infection. If there is an obstruction from scar tissue in the ureter (ureteral stricture) repeated dilation of the ureter with bougies may be necessary to open the ureteral lumen so that the urine can drain normally. Pelvic lavage, the procedure of flushing out the renal pelvis with antiseptics introduced through a ureteral catheter is helpful in promoting the immunity of local tissue by producing round cell infiltration in the wall of the pelvis and ureter. Inorganic silver solutions (silver nitrate from 0.5 to 5 per cent) are most effective. Irrigation of the renal pelvis and calices with a solution of penicillin containing 100 units per cubic centimeter has given beneficial results in *coccal* types of pyelonephritis. Dilation of a urethral stricture sometimes relieves the stasis in the bladder which is the source of both renal and vesical infection.

4 Elimination of foci of infection in other parts of the body is necessary to prevent the continued or recurrent flow of bacteria to the kidney. Tonsils, teeth, sinuses, appen-

dicitis, salpingitis, intestinal infections, osteomyelitis, respiratory infections, etc. must be properly treated.

5 *Operative measures* include all procedures necessary to insure removal of an overwhelming infection or perpetuate normal pelvic, ureteral or bladder emptying. Nephrectomy in severe infection, correction of hydronephrosis or abnormal renal mobility with kinking of the ureter, removal of renal or ureteral stone, excision of hypertrophy or sclerosis of the prostate and removal of diverticula of the bladder are all included in the possible surgical indications. Pyelitis occurring during pregnancy, pyelitis in infancy and defloration pyelitis are all subject to the same diagnostic and therapeutic principles enumerated. The last mentioned condition occasionally occurs in women following the first sexual intercourse and is presumed to be due to the absorption of infection attendant on rupture of the vaginal hymen.

INFECTION OF THE BLADDER (CYSTITIS)

Infections of the bladder may be acute or chronic, superficial, interstitial or pericyclic (involving the tissue surrounding the bladder).

Etiology—The common routes of infection are from the kidneys by way of the ureter and direct extension from the posterior methra. Less common routes are by way of the blood stream (hematogenous) and by a fistula between the bladder and some adjacent structure. The normal bladder is very resistant to bacterial invasion and inflammation of the bladder usually implies prolonged or severe descending infection, retention of urine, congestion or predisposing trauma.

The infecting organisms correspond with those of the kidney and renal pelvis above but with the addition of the gonococcus which in fact invades the trigonal structures and rarely produces a diffuse cystitis. Syphilis of the bladder, amebic cystitis and bilharziosis are very rare afflictions except in isolated localities and are hematogenous in origin.

The *predisposing factors* which favor localization of bacteria in the bladder are (a) all the various causes of residual urine, (b) pregnancy, cold foci of infection and (c)

trauma from prolonged overdistention (as after surgical operations) and the introduction of unclean instruments or strong corrosive solutions

Causes of Residual Urine in the Bladder
—Common to Male and Female—Bladder Obstruction due to tumors diverticula stones foreign bodies Urethra Obstructions due to stricture and tumor *Atony of the detrusor muscles* of central origin as in tabes multiple sclerosis myelitis or syringomyelia or from pernicious anemia from trauma to the cord or spine or from a tumor of the spinal cord

Male Only—Obstructing prostate benign and malignant median bar sclerosis of the vesical orifice urethral diverticulum or foreign body and phimosis

Female Only—Cystocele pressure from a uterine tumor prolapse of urethra and uterus and following parturition

Pathology *Acute cystitis* is characterized by hyperemia of the mucous membrane dilated capillaries small areas of submucous hemorrhage and patches of localized edema The mucosa may be partially covered by a fibrinous exudate or small superficial ulcers may be extensive with sloughing or even gangrene In *chronic cystitis* the lesions are variable The mucosa may be regularly thickened and hyperemic with marked localized areas of edema There may be white patches and formation of the epithelium (leukoplakia) or minute cystlike formations along the course of the blood vessels (cystitis cystica) If the urine is alkaline there may be ulcerations covered with crusts of calcium salts (crystalline cystitis)

Interstitial cystitis or Hunner's ulcer is a chronic inflammation which occurs in the subepithelial portion of the bladder involving the submucosa and muscularis but to a less extent the mucosa The involved areas are sclerotic and elastic and when the bladder is distended the mucosa cracks and bleeds The lesion appears as a localized hyperemic area with striated dilated capillaries entering it and the center occupied by one or more minute ulcerations

Symptoms—Cystitis generally speaking is a symptom and not a disease Its presence is evidenced by painful frequent urination pyuria and occasionally localized pain and hematuria These symptoms vary according to the severity of the infectious reaction in the bladder and not according to the duration of the disease

Acute cystitis is of sudden onset with frequent and painful urination The disturbance may vary from mild burning on voiding associated with exaggerated day and night fre-

quency to a condition of violent pain and spasm with marked urgency and frequency There may be severe terminal bladder spasm and hematuria Pus is constantly present in the urine Except in interstitial cystitis there is no suprapubic pain and all the discomfort is referred to the neck of the bladder urethra perineum or glans penis

Chronic cystitis is usually a secondary lesion and the symptoms are those of a lessened capacity of the bladder and increased irritability of the sphincters Nocturia in general and dysuria therefore may be mild or severe The infections which occur when there is acid urine with the exception of tuberculosis are relatively mild symptomatically while alkaline cystitis is usually most painful and irritating

Incrusted ulceration of the bladder is due to a urea splitting organism which produces intense cystitis with ulcerations of the mucosa of the bladder These areas are covered with calcareous incrustations which cause marked frequency and spasmodic pain The urine is turbid and ammoniacal and contains lime salt grit

Interstitial cystitis Hunner's ulcer occurs in the vertex and lateral walls of the bladder The elastic wall is replaced by scar tissue in localized areas and the capacity of the bladder is greatly reduced Suprapubic pain marked urgency at times amounting to incontinence and hematuria on overdistention are the cardinal subjective symptoms The urine is usually clear and sterile and contains only microscopic blood with rare pus cells

Diagnosis—Cystitis is suspected by the history of frequency and dysuria and confirmed by the finding of pus in the urine No diagnosis is complete unless the character and source of the infection are determined unless the complicating or additional lesions are located and unless evidence is obtained as to whether one or both kidneys are involved Frequent and painful urination and deeply complicating pre-existing urethritis indicates that infection has extended to the posterior urethra and trigone In acute proctitis bladder symptoms indicate involvement of the mucosa of the bladder If fever exists with bladder symptoms either a complicating renal or prostatic infection is assumed

Pyuria and positive bacterial growth from the urine confirm the diagnosis. The presence or absence of residual urine in either sex should always be established. The reaction of urine and stained smears of the sediment help in the identification of the bacteria which should later be confirmed by culture. Pronounced bladder symptoms with little pus and no bacteria suggest either interstitial cystitis or tularemiosis.

Cystoscopy must be used when it is necessary to examine the kidneys and ureters and to differentiate the different types of cystitis, the presence of diverticula, stones, tumor, prostatic obstruction and other complicating lesions.

Treatment—Relief of cystitis depends on adequate treatment of the causative disease. This may require a complete survey of the urinary tract and allied organs. Palliative treatment in acute cystitis consists of rest in bed, forced fluids, alkalinization of the urine and sedatives. Some mixture of codeine and hyoseyamus serves best. Urinary antiseptics are not usually helpful in acute cases because of the dilution of the urine and alkalinization. Local treatment is rarely needed unless there is residual urine. In the latter case, interval catheterization or an indwelling catheter may be used with soothing antiseptic irrigations or instillations.

The treatment and special methods of diagnosis for chronic cystitis are the same as for renal infections and have been described fully. Local medication may be used to allay symptoms and hasten cure. Irrigations and instillations of soothing or stimulating solutions are not in vogue as previously but are occasionally effective. Chronic ulcers and localized inflammations of the bladder wall may be treated by cystoscopic fulguration or topical application of solutions of silver nitrate.

HYDRONEPHROSIS

Hydronephrosis is the term applied to a pathologic condition resulting from mechanical interference with the outflow of urine from the kidney. It is characterized by distention of the renal pelvis and calices and retention of urine and may eventually lead to atrophy of the renal parenchyma, destruction of function and conversion of the kidney into a fibrous sac. One or both kid-

neys may be involved. When unilateral it is usually the result of an obstructive lesion above the point of entrance of the ureter into the bladder; when bilateral it may be due to obstruction of both ureters but more often it is the result of mechanical obstruction at the outlet of the bladder. The urine retained in the hydronephrotic sac may be sterile or infected.

Etiology—1 *Obstructive lesions* (congenital or acquired, intermittent or continuous, complete or incomplete).

Kidney stones, aberrant vessels or bands exerting pressure on the upper ureter or pelvic tumors or ptosis of the kidney with kinking at or near the ureteropelvic junction.

Ureter stones, strictures, kinks and tumors, pressure from without by new growths, inflammation or a pregnant uterus, ligatures accidentally applied in pelvic surgery.

Bladder stones, tumors and obstructive prostatic lesions at the outlet.

Urethra, congenital valves, acquired strictures and stenosis of the external meatus.

2 *Paralytic lesions* (faulty innervation), injury to the spine (fracture) or in tumor of the spinal cord, etc., lesions of the cord, tabes dorsalis, myelitis, syringomyelia or spinal bifida, or late changes associated with pernicious anemia.

3 *Overgrowth of tissue* is the cause some times assigned to ureteral dilatation (megalo-ureter) for which no obstructive or paralytic cause can be demonstrated (supposed analogy to Hirschsprung's disease or megacolon).

Pathology—The renal pelvis is dilated in varying degree (the normal adult pelvis has a capacity of about 10 cc.) and the parenchyma is normal or progressively compressed by the back pressure. The dilatation may involve only half of the kidney. If there are two ureters or a single calyx may be obstructed. In early cases sections show flattened papilla and a thinner medullary zone and the tubules are dilated and distorted. In advanced cases only a thin smooth wall remains with fibrous septa remaining. The thin remaining cortex presents hypertrophy of the renal cells and glomeruli with marked sclerosis of the vessels. The size may vary from that of a normal kidney to a cyst like shell filling half the abdominal cavity.

Symptoms—The symptoms are extremely variable. There may be none unless the hydronephrosis is complicated by infection or the formation of a stone. Pain, pyuria and hematuria are usual symptoms. Occa-

sionally a tumor is felt in the loin or upper abdomen. Pain may be felt in the lumbar region and back or it may be referred to the abdomen with accompanying vague symptoms of nausea vomiting and disturbed digestion. It is usually of a dull aching character but when sudden added retention occurs it may become sharp severe and colicky.

Pus in the urine may be the only finding or an associated exstitis with frequency dysuria and hematuria may call for a study which may show that an infected hydronephrosis is the primary factor.

It should be emphasized that complete absence of both urinary symptoms and signs does not rule out the possibility of hydronephrosis and this condition should be borne in mind in the differentiation of all vague abdominal complaints of chronic or recurrent nature.

Diagnosis—Unfortunately even a large hydronephrosis is difficult to palpate accurately. When palpable the mass is that of a smooth elastic tumor usually felt in the loin by bimanual pressure and is not hard or nodular as in tumor or cyst of the kidney. The diagnosis must be confirmed by ureteral catheterization retrograde pyelography or excretion urography.

When the ureteral catheter is passed into the hydronephrotic sac there is a rapid flow of thin limpid urine and aspiration with a syringe shows the amount of retention. The excretion of dye is diminished in an amount corresponding to the extent of renal destruction. The roentgenograms demonstrate the outline of the dilated pelvis and calices and give an indication of the etiological factors.

Treatment—The method of treatment depends on the causative factor and the extent of destruction of renal tissue. The removal of obstructive lesions of the bladder and urethra may relieve renal dilatation from these sources (urethral meatotomy progressive dilation of a urethral stricture cystoscopic cautery destruction of valves electric resection of prostatic tissue or prostatectomy). It is advisable to discover obstructive lesions in the ureter or kidney before advanced renal destruction has occurred. In well advanced hydronephrosis if the other kidney is inadequate or if the dilatation is bilateral treatment must consist of such

measures as cystoscopic dilation of a stricture removal of a stone nephropexy or a plastic operation on the kidney or ureter. If one kidney is irreparably damaged and the other maintains its normal function nephrectomy should be performed. Occasionally when one half of a kidney is hydronephrotic as in obstruction of a major calyx heminephrectomy may be carried out. The latter procedure may also be indicated when there is hydronephrosis in half of a double kidney.

PERINEPHRITIC ABSCESS

Perinephritic abscess implies an infection outside the capsule of the kidney (paranephritis) with resultant necrosis of the perirenal fat and frank suppuration in the renal fossa.

Etiology—The perirenal space is infected through the blood supply which is independent of that of the kidney proper or by extension of infection from the kidney itself or by contiguity from adjacent structures. The primary organism is usually the staphylococcus although the colon bacillus may be a secondary invader. The primary focus is most commonly a cutaneous infection such as a furuncle carbuncle cellulitis or paronychia. Respiratory foci and infections in the mouth also contribute but in lesser degree to perirenal infection. Chronic cortical abscess carbuncle of the kidney pyonephrosis and contiguous intra-abdominal suppurations constitute the locally direct causes.

Pathology—The perirenal fat becomes edematous thickened and infiltrated. Minute areas of suppuration coalesce to form larger areas of liquefaction and eventually the entire renal fossa may be filled with pus.

Symptoms—The constitutional manifestations of perinephritic abscess are much like those of infections in the renal cortex. The onset is insidious and suggests "grippe" or respiratory infection without localizing signs. Fever is intermittent and chills and sweats may be frequent but local symptoms are commonly not pronounced until the suppuration is marked. Leukocytosis is high and the urinary findings are normal unless the infection breaks through to connect with the urinary tubules. With the patient lying on his back or sitting a definite fullness may be noticed in the loin of the affected side. When the condition is well advanced the

mass in the loin is fixed and diffuse in outline. When the abscess is confined to the kidney the mass may be movable and more easily outlined. Pain is usually limited to the costovertebral region. Occasionally the abscess develops very rapidly producing septic symptoms which necessitate immediate incision and drainage. In such a case there is bulging in the loin and retroperitoneal extension downward producing distention and pyrexia of the intestines. There is often edema of the overlying tissues.

Diagnosis—In the early stages the diagnosis is not easy and must be arrived at after sufficient time has elapsed so that other septic conditions can be carefully excluded. One may often suspect perinephritic abscess from the history and vague physical findings but may be unable to decide definitely until some localizing signs appear. The history of prior infections and the intermittent and vague course of fever, malaise and backache associated with marked leukocytosis when supplemented by localized tenderness in the loin suggest perirenal suppuration. In the early stages the urine may be normal and signs of infection may gradually develop or the analysis may be normal throughout. Ureteral catheterization and renal function tests help little or not at all. The roentgenographic findings are most helpful. Scoliosis is the most important sign, the curvature being away from the involved side and probably resulting from contraction of the spinal muscles near the suppuration. Obliteration of the marginal outline of the psoas muscle is also important and may appear early. Of course any enlargement of the kidney may produce this, such as that due to a nephroblastoma, cyst and hydronephrosis, but as a rule the clinical picture is different. When great liquefaction occurs the entire shadow of the kidney and the outline of the psoas muscle are obscured by a homogeneous density on the affected side. Upward displacement of the diaphragm, distortion of the ureteral outline and anterior displacement of the colon also may be evident.

Treatment—Incision through an approach in the costovertebral region must insure free retroperitoneal drainage and complete evacuation of the abscessed areas. In rare instances it is necessary to expose the kidney so as to drain the localized

pockets or to inspect the cortex of an abscess or carbuncle. In the main a rapid cure without complications is the result.

TUBERCULOSIS OF KIDNEY, URETER AND BLADDER

Tuberculosis of the urinary tract begins in the kidney but is always a secondary lesion caused by the deposition of tubercle bacilli from the blood stream. The respiratory system is most frequently the original focus, nodes in the hilum giving off bacilli which enter the blood stream through the lymphatic duct. Mediastinal, cervical and mesenteric nodes are therefore the common original foci. Modern evidence controverts the old theory that a healthy kidney may filter tubercle bacilli into the urine from the blood stream. A lesion is always present in the kidney when bacteria are revealed in the urine excreted by that kidney. It is possible that renal tuberculosis is frequently a bilateral condition in its inception but that one kidney resists the infection while the other succumbs, resulting in the more common clinical condition of unilateral disease. Tuberculosis is one of the most destructive of renal lesions. The kidney is involved in about 10 per cent of all patients dying of tuberculosis and in 1 per cent of all autopsies.

Etiology—*Surgical tuberculosis* of the kidney is predominantly a unilateral condition. Clinically it is bilateral in about 20 per cent of the cases while autopsy shows bilateral infection in 50 per cent. It is probable that if careful serial sections were made in this latter group a high percentage of small healed lesions would be found. The disease is most common in early adult life between the ages of eighteen and forty but may occur at any age. Usually no predisposing cause can be determined but it is probable that trauma and stasis play a part in other infections of the urinary tract.

As already stated tuberculosis of the kidney is a secondary process but the primary lesion is not evident in some 75 per cent of the patients seen clinically. Genital lesions in the male are associated in from 50 to 60 per cent of cases.

Pathology—The lesion begins as a tubercle in the renal cortex or pyramid. The initial pathology is that of a collection of round and giant cells surrounded by an area of fibrosis. As the condition progresses, casea-

tion and cavity formation and invasion of the pelvis ureter and bladder are noted. The disease spreads throughout the kidney via the intertubular lymphatics and multiple nodules and caseous cavities may occupy renal tissue or may dot the surface of the kidney or ureter. If the cavities coalesce the kidney may become a mere shell. Ulceration and thickening of the ureter may obstruct the kidney and result in pyonephrosis. Occasionally the descent of the process is halted by complete tuberculous occlusion of the ureter a condition termed antonephrectomy. If the lesions are less destructive a small contracted kidney may result and in this event there is fibrotic replacement of the cortex with fatty infiltration. Calcification may occur in the caseated areas. The ureter is secondarily infected from the kidney and ulceration thickening of the walls tortuosity and stricture formation occur. Involvement of the bladder occurs very early at first a superficial invasion of the mucous membrane later extending to the submucous layers. The process often begins about the corresponding ureteral orifice as a red loosed edematous area later small tubercles may cover this region. These caseate and ulcerate and as fibrosis occurs the ureter retracts the orifice remaining patulous (golf hole appearance). Large submucous areas of the wall of the bladder become fibrotic and contraction of the bladder with marked diminution of capacity results.

Symptoms—The earliest and most persistent symptom of renal tuberculosis is frequency of urination. An associated polyuria causes this frequency to be decidedly more annoying at night. As ulcerations appear and the vesical wall is invaded the frequency is accompanied by pain which at first is terminal but later becomes continuous. Urination becomes more and more frequent as the capacity of the bladder diminishes. Occasionally the bladder becomes so contracted that incontinence ensues. Hematuria either microscopic or gross, is evident from the start and occasionally a profuse hemorrhage from the kidney is an initial symptom. Renal pain is rarely found as an early symptom and may in fact never develop. There is often an aching sensation felt deeply in the loin and aggravated by exertion or jolting. Renal colic can occur from the passage of blood or inspissated pus clots. There may be tenderness over the region of the kidney on deep palpation first percussion of the back may elicit local pain and occasionally an enlarged kidney is outlined. The general symptoms may be fever, night sweats, loss of weight and digestive disturbances.

Diagnosis—Tuberculosis should be suspected in any young or middle aged person who complains of nocturia and progressive

frequency of urination. Unless hematuria occurs the urine is clear and acid and usually contains no ordinary pyogenic bacteria. Late in the disease secondary infection may occur but is not common. The diagnosis is determined by the finding of tubercle bacilli in the urine and by localization of their source by cystoscopic examination and ureteral catheterization. Urine must be obtained so that the smegma bacillus which is also acid fast does not contaminate the urine. Careful external cleansing in the male and catheterization in the female will obviate this difficulty. The lesions in the bladder as seen at cystoscopy are usually suggestive and examination of the urine from either kidney will show the presence of infection and the functional excretion of dye. If the bacilli are not easily identified in smears from the urine it may be necessary to culture the urine on special media or to inject it into a guinea pig as a culture medium. Ureteropyelography may show dilatation tortuosity and stricture of the ureter and moth like filling defects in the outline of the renal calices. The isolation of the organisms is often tedious and difficult even after one feels sure that tuberculosis exists. The functional condition of the unaffected kidney must be carefully studied. In the differentiation such local causes of vesical irritation as prostatic infection, stone, stricture and gonorrhea are easily recognizable and these usually respond to local treatment whereas tuberculosis does not. The greatest difficulty in diagnosis is encountered in cases of chronic low grade pyelocystitis of pyogenic origin and in interstitial cystitis a persistent disease associated with a contracted bladder and sterile urine.

Treatment—A patient with bilateral renal tuberculosis must be treated as in severe advanced pulmonary tuberculosis. In these cases the prognosis is to cure is usually hopeless although the patients may live miserably for a number of years. While early spontaneous healing may occur such a result is practically never seen if the symptoms are severe enough to bring the patient to a doctor. Removal of the affected kidney (nephrectomy) in unilateral cases is followed by a clinical cure in from 60 to 75 per cent of cases depending on the extent of the disease and the environment for con-

valescence. The same medical and hygienic care that is accorded all tuberculous patients should be followed in cases of tuberculosis of the urinary tract. In some instances it is well to remove the ureter as well as the kidney on the affected side. Tuberculosis of the bladder may persist after nephrectomy and presents a serious problem. The judicious use of tuberculin, preferably given intradermally, seems helpful as a postoperative procedure.

TUBERCULOSIS OF THE EPIDIDYMIS

Tuberculosis of the epididymis is a frequent lesion but involvement of the testis is rare. An unsettled controversy continues as to whether the original genital focus is in the epididymis or in the prostate and seminal vesicle. Since combined lesions of these structures usually occur, it is usually impossible to be sure in which organ the tuberculous process commenced. Genital tuberculosis as renal is always secondary to tuberculous elsewhere in the body. Whether the tubercle bacilli reach the epididymis through the blood stream or whether the process occurs secondary to a preexisting focus in the prostate and seminal vesicles is of academic importance. Both routes are probable. The local testicular process usually begins in the globus major as a more or less painless hard nodule which enlarges gradually and is accompanied by nodular headlike thickening of the vas deferens. In the malignant slow lesions there is gradual enlargement of the entire epididymis followed by nodular enlargement of the scrotal skin and multiple purulent abscess formation. Rarely acute testicular epididymitis occurs which is difficult to differentiate from gonorrhea or nonspecific infection. The entire epididymis becomes acutely swollen and tender, scrotal redness and inflammatory lymphocytic infiltration cause a swift enlargement. These acute reactions usually subside with rest and palliative treatment. The process then resembles the reaction of gonorrhea.

The differential diagnosis includes all conditions which cause scrotal enlargement. Preoperative treatment is directed to careful hygiene, rest, and chemotherapy. Graduated injections of old tuberculin intradermally and proper dietary measures. Surgical excision of the epididymis and a portion of the vas deferens with preservation of the testis should be done only after the acute reaction has subsided and the general resistance of the patient has been increased. Genital tuberculosis accompanies renal and vesical lesions in from 90 to 30 per cent of cases.

ANTERIOR URETHRITIS IN THE MALE

The term *urethritis* indicates infection of the urethral mucous membrane and its associated crypts and glands. The term *anterior urethritis* designates the condition in which the involved area extends only to the triangular ligament (external sphincter) leav-

ing the membranous and prostatic portions unaffected.

The anterior urethra most commonly becomes infected from outside the body and through the external meatus. The gonococcus, trichomonas and colon bacillus are the usual invaders and are most frequently introduced during the sexual act.

Secondary infection of the urethra occurs by contiguous means from adjacent upper genital or urinary structures or by contamination of infected urine. Pelvic exstis and prostatitis are the common contributing sources. Colon bacillus, streptococcus, staphylococcus and more rarely the pneumococcus are the exciting organisms. Tuberculosis of the male urethra is rare but occurs occasionally secondary to extensive genital and renal infection.

Urethritis is said to be *specific* if caused by the gonococcus and *non specific* if due to other organisms. Intraurethral chancre (primary lesion of syphilis) is not to be considered as a urethritis in the strict sense.

In general the causative factor of urethritis is (1) bacterial, (2) chemical or (3) traumatic. Chemical and traumatic causes constitute merely additional primary reactions in the urethral mucosa which lower the vitality of the tissues and allow bacterial urethritis to supervene. Thus the injection of caustics and the effects of external or internal injury pave the way for bacterial growth within the urethra and should not be described as separate types of urethritis.

The urological aspect of the diagnosis and treatment of urethritis is to be found in texts on genitourinary diseases and only the surgical complications which may arise in the course of the various types of infection will be considered here.

Complications of Anterior Urethritis.—Balanitis, phimosis, lymphangitis, periurethritis, periurethral abscess, inguinal adenitis and urethral fistula are the most common complications and arise secondarily to gonorrheal infection in greater frequency than from non specific infection.

Balanitis is a diffuse inflammatory reaction in the preputial skin with swelling, edema and redness due to lymphatic obstruction. The diagnosis is self evident and treatment consists in frequent cleansing of the parts, prolonged application of hot

moist compresses to promote absorption and proper attention to the urethral infection. All patients with balanitis should be carefully examined in order to discover the possibility of an underlying chancre as the concealed cause rather than the obvious urethritis. If the swelling does not subside promptly and if there is any evidence of necrosis or sloughing of the skin the condition is more probably due to an anaerobic infection caused by the spirillum this condition being called *erosive and gangrenous balanitis*. Continuous diligent application of peroxide potassium permanganate or other oxidizing antiseptics must be employed to prevent extensive destruction. Surgical incision is rarely if ever indicated in balanitis.

Phimosis designates localized swelling, tightness and irretractability of the terminal preputial skin. This results in retention of urethral discharge and secretion and may excite balanitis and lymphangitis. Hot applications, cleansing irrigations and repeated attempts to loosen and retract the foreskin should be tried but if they are not quickly successful the foreskin should be incised over the dorsum of the penis. This *dorsal slit* is made with infiltration anesthesia and a few sutures of silk or catgut are used to approximate the cutaneous surfaces. Circumcision if indicated should be done at a later date when the acute inflammatory reaction has subsided.

Lymphangitis is characterized by hard cord like infiltrations in the dorsal and lateral skin of the penis due to inflamed and obstructed lymphatics which may appear as red lines sometimes reaching 1 cm. in diameter. Hot fomentations, medical diathermic heat and rest of the parts usually result in softening and improved drainage in from three to five days. These areas should never be incised surgically unless secondary infection occurs.

Inguinal adenitis results from regional infection and may be found with or without secondary balanitis, phimosis or lymphangitis. The nodes in one or both groins become enlarged and tender. Rest and induced heat combined with proper local treatment usually result in prompt subsidence of the adenitis. In some cases however the glands break down become fluctuant and require surgical incision and maintenance of proper

drainage until healing has occurred. Adenectomy is not advisable unless repeated suppurations of a low grade character persist for some times.

Periurethritis evidences itself by the appearance of localized nodular infiltrations along the ventral aspect of the penis. This condition is due to localized retained infection in a periurethral gland. Hot applications of induced heat by medical diathermy result in absorption, urethral drainage or the formation of a localized *periurethral abscess*. This condition appears as a rounded fluctuant ball or mass on the floor of the urethra. Incision and drainage without entering the urethra itself is advisable. This localized area then either heals and becomes obliterated by fibrous tissue or the mucosal elements grow down from the urethra to the skin and form a *urethral fistula*. This latter condition may prove most troublesome in that there is leakage of urine and irritation and also that the fistulous tract offers an ideal area for persistent harboring of gonococci. The fistulous tract may be closed by repeated cauterization with solution of silver nitrate or other caustics. Coagulation of the tract by the actual cautery or by a wire electrode of high frequency current is often successful. If these measures fail excision of the tract and careful closure of the urethral floor and outer skin in separate layers is indicated. In rare instances when the urethral defect is extensive it is advisable to divert the urine by perineal drainage or suprapubic cystostomy for two or three weeks in order to permit the operative site to heal permanently.

VINCENT J. O'CONNOR

INJURIES TO THE KIDNEY

Contusions, rupture and bullet wounds of the kidney are of great importance. Although the kidney is fairly well protected from trauma by its location and mobility, injuries to it are more common than formerly mainly because of the increasing frequency of automobile accidents. Athletic sports also contribute their share of renal injuries.

The mechanics involved in contusion and rupture of the human kidney are best demonstrated by experimental studies. In the writer's experiments it was found impossible

to rupture the fibrous capsule of a dog's kidney by striking its surface with a blunt instrument although various degrees of injury could be inflicted on the cortex depending on the force used. The injuries produced varied from light subcapsular hemorrhage to complete pulpefaction of the traumatized portion of the cortex.

Pathology—When the fibrous capsule is opened following injury, brisk bleeding at once occurs and in the case of severe injury, serious hemorrhage is noted. In every case in which operation is performed early, this is readily controlled by applying thin particles of fat to the region of the bleeding points and repairing the wound by the use of plain ribbon gut fixed in position by means of straps made in the fibrous capsule.

After actual pulpefaction of a portion of the renal cortex, the tissue does not seem to break down and produce an abscess unless the fibrous capsule remains intact. In the latter event the continued hemorrhage and the influence of extravasated urine from the ruptured and macerated cortex result in the ultimate rupture of the fibrous capsule owing to its digestion by the ferments released under it and abscess formation. This usually occurs some time after the injury which in itself may not have been considered severe.

Symptoms—Pain at the site of injury is the most prominent symptom of trauma of the kidney. This is usually accompanied by microscopic blood in the urine and if the bleeding is severe there will be the cardinal signs of gross hemorrhage: rapid pulse, air hunger, pale worried faces and a cold clammy skin. Swelling may be noted on the affected side and tenderness is always present. Absence of blood in the urine does not rule out injury to the kidney for this may be due to severance of the ureter or its complete blockage by a blood clot.

Prognosis—The prognosis is favorable if operation is performed early in severe lesions. If hematuria persists for more than twenty-four hours the kidney should be explored and drainage instituted.

Symptomatic Treatment—The pain accompanying even slight traumatism of the kidney is usually such that a strong sedative such as 1 grain of codeine or $\frac{1}{4}$ grain of morphine is indicated. The patient should

be immediately hospitalized and the general condition carefully observed for increasing evidence of shock and hemorrhage.

Indications for Operative Treatment—Experience with experimental rupture of the kidney leads to the belief that many cases of renal injury are fatal because the surgeon does not operate soon enough. If shock is great the patient should be prepared by the giving of stimulation in the form of hot coffee, enemata, adrenalin, cardiac stimulants and blood transfusion and relieved of pain by sedatives. Exploration under spinal anesthesia should be carried out at the earliest safe moment. If the injury has not been grave at the outset but hematuria con-

Fig. 6.0—Completed repair of a rupture of the kidney showing the drain in the pelvis of kidney and fat inserted into the ruptured bleeding portion of the cortex. Pressure sufficient to produce hemostasis is exerted by the ribbon gut.

tinues for longer than twenty-four hours the kidney should be explored. Even if there is no hematuria but the patient becomes lethargic and tenderness or swelling or both persist in the loin, an exploratory operation is advisable. When in doubt, always operate.

Principles of Operative Treatment—The kidney is exposed in the usual manner and isolated from surrounding structures. (In cases of serious renal damage the fibrous capsule will be elevated by the underlying hematoma and the damage to the underlying renal cortex can be both seen and felt.) The capsule is opened, blood clots are sponged away and isolated wedges of

cortex are removed. Bleeding points are controlled by applying pieces of fat under pressure while plain ribbon gut is fixed in position about the kidney by means of straps made in the fibrous capsule. The ribbon gut is then tied with sufficient pressure to control the bleeding. A rubber drainage tube is passed into the renal pelvis before the ends of the ribbon gut are tied. Penrose drains are placed around the kidney to take care of the fluids that collect there, and the wound is closed in layers in the usual manner.

INJURIES OF URETER AND BLADDER; FOREIGN BODIES AND ULCERS OF THE BLADDER

WOUNDS OF THE URETER

Wounds of the ureter, with the exception of those incidental to surgical procedures are extremely rare in civil practice. Even in military practice they are relatively rare in comparison to wounds of other intra abdominal organs. This is readily explained since they are well protected by their deep location and moderate mobility.

A few cases have been reported in which the ureter has been perforated by instruments introduced through the cystoscope, and there are one or two cases on record in which an impacted calculus has sloughed through the ureter wall with resulting extravasation and abscess formation. It has been fairly clearly demonstrated that it is impossible to apply enough pressure through the cystoscope to perforate a normal healthy ureter with an ordinary catheter. This however does not apply in the case of the diseased ureter. Metal instruments such as dilators forceps stone extractors etc. may and occasionally do perforate the normal ureter.

This is obviously a cogent argument against their indiscriminate use. The great majority of ureteral wounds occur in the course of surgical procedures particularly operations deep in the pelvis totally abdominal pan hysterectomy or vaginal hysterectomy. Many gynecologists when about to undertake what promises to be a difficult hysterectomy adopt the very wise procedure of passing catheters into each ureter before operation. These serve as a valuable guide to the location of the ureter in deep pelvic operations and naturally lessen the likelihood of injury. These accidents occur rather commonly doubtless much more frequently than would appear from the literature since many cases are never reported. In fact it is quite possible to include one ureter in a ligature with no obvious untoward effect other than a moderate amount of pain or discomfort referred to the corresponding loin and this symptom would be masked by the usual postoperative discomfort incidental to any major surgical procedure. In such an event if the kidney is not infected there would be a temporary hydronephrosis followed by atrophy of the kidney. The remaining kidney could take over the entire renal function and the patient might go on to an apparent smooth recovery with a dead kidney on one side and live but less normal life expectancy totally ignorant of the fact that an accident had occurred.

Accidental operative trauma to the ureter might consist of complete ligation of one or both ureters, needle puncture with partial inclusion of the ureter caliber in the ligature cuts or tears of varying degrees in the ureter walls and finally the ureter might be entirely cut across. There is still another type of case which should perhaps be included in this group and that is the occasional case of periureteric fibrosis with resulting occlusion of the pelvic ureter following the use of radium in the treatment of carcinoma of the cervix uteri.

Symptoms.—Operative wounds of the ureter, except when the ureter is entirely cut across are often not recognized at the time of accident. Complete section is usually but not always recognized at once. Complete ligation of both ureters would of course be followed by complete anuria together with pain and a sense of fullness in both loins. In cases in which the lumen of one or the other or both ureters has been opened and the flow of urine not blocked by a ligature there would be the usual symptoms of a deep pelvic infection varying in degree in inverse proportion to the amount of drainage instituted at the time of operation. In cases with no drainage the infective symptoms are fulminating and severe chill fever sweating prostration nausea, vomit

ing and other evidences of acute peritonitis appear, in fact, all the symptoms of an extensive intraperitoneal and extraperitoneal extravasation of urine. Since most of these accidents occur in the course of a panhysterectomy, where adequate drainage, usually vaginal is always provided the symptoms of infection are very mild and transitory in character and may pass unnoticed. In these cases there will be from the beginning a constant seepage of urine mostly from the vagina occasionally also through the abdominal wound. This condition is often not recognized until a period of days or even weeks has elapsed following the operation. The constant vaginal discharge may at first be attributed to serous discharge and later to a mild degree of incontinence.

Diagnosis—The diagnosis should be readily made if the possibility of surgical accident is borne in mind. In cases of urinary leakage from the vagina, it is of course necessary to differentiate between wounds of the ureter and wounds of the bladder.

This is readily accomplished by the following simple procedure. The patient is placed in the lithotomy position a vaginal speculum inserted and the vagina sponged dry, a soft rubber catheter is then passed into the bladder which is then distended with some colored fluid such as a solution of methylene blue. If the blue fluid is noted escaping into the vagina it of course proves that there is a rent in the bladder wall. Conversely if no blue appears in the vagina and urine does appear it is fair to assume that the lesion is in one or the other ureter. In all cases it will be necessary to make a careful cystoscopic examination perhaps also a roentgenographic study for the purpose of determining which ureter is involved. On the normal side a catheter will pass easily to the renal pelvis whereas on the involved side it will be blocked a short distance from the bladder. If there is any doubt a large catheter may be passed a short distance into the suspected side and skidman inserted. A roentgenogram will show the opaque fluid irregularly diffused in the surrounding area.

Treatment—If a wound in the ureter is recognized at the time of operation and the organ is not entirely cut across it may be closed in part with a very fine plain gut suture care being taken not to constrict the lumen and to provide adequate drainage. This latter is of course of vital importance. In fact drainage alone without the suture may be all that is required. Ureter wounds heal very kindly if given a chance.

When the ureter is cut entirely across and the accident is recognized at once, several methods of repair are possible.

The procedure of choice should be an effort to reunite the cut ends and reestablish the normal urinary stream. It is absolutely essential that the anastomosis be made without tension. If the ureter has been divided very close to the bladder wall it may be better practice to tie off the distal end and reanastomose the proximal end at a higher point in the bladder. If the cut has been made higher up and it is impossible to approximate the two ends without undue tension one may revert to another expedient the feasibility of which has been recently demonstrated on experimental animals. A large catheter is passed through the bladder and distal portion of ureter then guided into perineal position to the renal pelvis the cut ends are anastomosed in this position with a few sutures loosely placed. The catheter is left in situ for several days. In the experimental animals a new tubular structure lined with epithelium has regenerated. Many operators have tied both ends and simply dropped them in the wound. If the corresponding kidney is not infected and the remaining kidney is sound it is reasonable to expect a smooth recovery. Adequate drainage is of vital importance in all cases and one must be prepared to perform nephrectomy later if occasion arises.

In cases in which the accident is not recognized until after operation the condition generally becomes apparent immediately. Occlusion of one ureter usually requires no treatment other than watchful waiting. Complete occlusion of both ureters naturally requires prompt action.

One may reopen the abdomen and carry out a debridement. This however is often very difficult and is attended by profound shock. It is much safer and better to perform bilateral nephrostomy or pyelostomy under local anesthesia. Often the catheter of the ureters will be restored spontaneously after a period of several weeks following which the pyelostomy fistula will heal. An open wound of the ureter which drains into the vagina should not be attacked surgically until a period of several weeks has elapsed following the original operation. If the ureter is completely cut across the proximal ends should be exposed through an extra-peritoneal incision and reimplanted in the bladder. Lateral wounds occasionally heal spontaneously. Recovery may be hastened if a catheter can be passed beyond the lesions and left in situ for several days. This procedure may be repeated from time to time. If any or all of these methods fail the urinary leakage can always be promptly cured by nephrectomy if the functional integrity of the remaining kidney is normal.

WOUNDS OF THE BLADDER

The bladder may be accidentally wounded in the course of operative procedures on neighboring organs such as abdominal or vaginal hysterectomy or plastic operations.

in the vagina. The bladder is occasionally found as a part of an inguinal or femoral hernia and has at times been wounded at operation. Other than operative trauma the bladder may be the seat of penetrating wounds such as from a stab or a bullet. More frequently however it results from a crushing injury often associated with fracture of the pelvic girdle. A severe abdominal contusion may result in a ruptured bladder particularly if the organ is distended at the time of the accident. The wound may be extraperitoneal or intraperitoneal or both.

Symptoms—Shock of varying degree is always present particularly in cases due to crushing accidents. As the patient rallies from shock attention will be directed to the bladder by bloody urine pain and tenderness over the bladder varying degrees of frequency tenesmus and strangury or a complete inability to void. In extraperitoneal rupture these symptoms are followed very soon by all the signs of urinary extravasation and sepsis. In cases in which the rupture is directed into the peritoneal cavity there may be a temporary lull in the symptoms that is soon followed however by all the signs of intense and fulminating diffuse peritonitis and recurrence of profound shock.

Diagnosis—In any case of crushing injury or severe contusion of the pelvic region particularly if associated with any disturbance in the act of urination rupture of the bladder should be strongly suspected. If the patient is unable to void and catheterization is indicated this should be carried out under very strict aseptic precautions and the surgeon should be prepared to perform a suprapubic drainage at once if indicated. The writer does not approve of cystoscopy in these cases. An intravenous urogram may assist in establishing the diagnosis. If there is any doubt an exploratory operation is clearly indicated.

Treatment—The treatment may be summed up in the one word—*drainage*. This should be prompt and adequate. If the rent is intraperitoneal it should be closed the peritoneal cavity freely drained with drains deep in the pelvis the bladder drained extraperitoneally and the patient placed in the Fowler position. If the tear is extraperito-

neal the bladder and the perivesical area should be very freely drained. The perivesical area requiring drainage will usually have been converted into more or less of a distinct cavity by the extravasated urine.

FOREIGN BODIES IN THE BLADDER

All manner of foreign bodies have been reported from time to time as having been found in the bladder splinters of bone from a fractured pelvis bits of suture material or gauze drains broken ends of catheters or drainage tubes wax tapers small lead pencils (the two latter often introduced by the patient for purposes of masturbation) etc. The diagnosis is established by the history (not always easy to obtain) the symptom of frequent and painful urination plus cystoscopic and roentgenographic studies. In the great majority of cases if an early diagnosis is made the foreign body can readily be removed by cystoscopic manipulation. If allowed to remain for any length of time a foreign body becomes covered by a deposit of urinary salts it grows in size by accretion and it requires removal by means of suprapubic cystotomy. In other words it becomes for all practical purposes a vesical calculus.

VESICAL CALCULI

Calculus of the bladder is one of the most ancient and venerable of all surgical diseases. Stones have been found in the bladders of Egyptian mummies. The subject has been discussed by all surgical writers beginning with the earliest periods recorded in history.

Etiology—The most commonly accepted theory of urinary calculus is that there is a disturbance in the colloidal content of the urine as a result of which the crystals are thrown out of solution. A deficiency of vitamin A in the diet appears to have some effect in reducing the necessary colloidal content of the urine. For a full and complete discussion of these phases of the problem the reader is referred to Joly's textbook on *Stone*. There are two other factors which predispose to the formation of stone in any part of the urinary tract particularly in the bladder. First an obstruction to the normal current or flow of urine. Vesical calculi are noted far more frequently in males than in females owing to the fact that obstruction at the neck of the bladder in the urethra is noted much more commonly in the male. Many calculi are formed originally in the kidney from whence they are passed with accompanying colic to the bladder. While most of these stones are voided spontaneously if there is any obstruction to the flow of urine from the bladder

they remain and increase in size by accretion. This type of stone usually has a nucleus of calcium oxalate or uric acid with outer layers of calcium phosphate and carbonate. The majority of vesical calculi consist entirely of carbonates and phosphates and are formed originally in the bladder, usually in the presence of obstruction or infection or both. Any foreign body introduced or left in the bladder by accident will in time become encrusted with a layer of urinary salts and will become a calculus.

Symptoms.—The outstanding symptom of calculus of the bladder is frequency of urination, worse by day and when the patient is moving about. This is in rather sharp contrast with urinary frequency in cases of renal or vesical tuberculosis, which is worse at night. Urination is frequently painful, and often there is a tendency for the stream to start and stop several times during the act. Bloody urine is often noted, occasionally in the form of a gross hematuria with blood intimately mixed with the urine more fre-

the bladder. Very large calculi may occasionally be palpated via the rectum or vagina, rarely even suprapubically. The diagnosis should always be confirmed by cystoscopic investigation, which is readily and easily accomplished. Large and perhaps even small calculi will show in roentgenograms.

Fig. 652.—The bladder is exposed and is readily recognized by its large veins and decussating muscle fibers. The peritoneal fold is being stripped back.

Fig. 651.—Multiple vesical calculi also showing urethrograms and large prostate. The calculi were removed by suprapubic cystotomy, followed later by suprapubic prostatectomy.

quently in the form of a terminal hematuria. Microscopic examination almost invariably shows red blood cells, together with pus in varying amounts.

Diagnosis.—The diagnosis is strongly suggested by the very characteristic symptoms. Occasionally the grate of a calculus may be felt when a catheter is passed into

grams (Fig. 651). It is to be noted however, that a negative roentgenogram does not exclude the presence of vesical calculi. This may be accounted for by the low density of the calculi or their situation behind the pubic bones so as to obscure the picture.

Treatment.—Stones which are not too large or too numerous may be removed transurethrally by means of crushing and evacuation with the Bigelow evacuator. Multiple stones or single stones exceeding an inch in diameter should be removed by suprapubic cystotomy. Crushing or litholapaxy, until recently, was always done with a Bigelow lithotrite. In the hands of an expert it is a very safe and reliable instrument, and many operators even today still employ it as a matter of preference. Most urologists, however, at the present time prefer to crush the stone under direct vision using one of the many cystoscopic lithotrites in common use. Whichever instrument is used, sacral or transsacral novocain provides the ideal anesthetic. The writer feels that all these patients should be hospitalized

for a few days. One should proceed methodically and patiently with repeated crushing and washing until it is assumed that every vestige of calculus has been removed. This should be confirmed by cystoscopic inspection. While small particles may be evacuated spontaneously, their continued presence may provide the nucleus for a recurrence.

All large and multiple calculi are best removed by means of suprapubic cystotomy. This is easily carried out under local or field block anesthesia. The bladder is irrigated and distended with some bland solution such as 2 per cent boric acid. A 3 inch midline incision just above the symphysis is carried through the various layers of the abdominal wall down to the bladder which is easily recognized by the large veins and decussating muscle fibers. The peritoneal fold is stripped back and the bladder opened and evacuated through a small incision near its summit. This incision may later be enlarged if the size of the stone demands it. The stone is removed and the bladder carefully investigated by touch and sight for any complication such as tumor, diverticulum, obstruction of the neck, etc. If there is an obstruction at the neck of the bladder such as an enlargement of the prostate it is well to correct this at a later date. Otherwise calculi are apt to re-form. If the bladder has not been grossly infected and the vesical wound has not been too badly traumatized by the removal of a very large calculus, primary union may be attempted by closing the wound tightly with interrupted chromic sutures. In this event an indwelling catheter should be left in the urethra and a cigaret drain in the space of Retzius. If successful this of course shortens the period of convalescence. However in the great majority of cases it is wiser to leave a rubber tube in the bladder for drainage. This may be removed at the end of a week following which the sinus will heal promptly provided there is no obstruction to urination.

ULCER OF THE BLADDER

Vesical ulcers are rather frequently noted as an expression of other forms of underlying pathology such as severe forms of cystitis, vesical tuberculosis, sloughing carcinoma, etc. These are best considered under their respective headings.

The two types of ulcer most frequently noted as separate and distinct pathologic entities are radium burns and the so-called elusive ulcer first described by Hunner.

Radium Burns—Radium burns occur not infrequently following the use of large doses of radium for vesical neoplasm or even small doses in very susceptible persons. The symptoms are frequency, dysuria and occasional hematuria.

Diagnosis—It is obviously of vital importance to differentiate between a radium burn and extension or persistence of a sloughing carcinoma, yet it is often an extremely difficult diagnosis to make. In both instances the cystoscopic picture may be that of a dirty gray sloughing slightly elevated area. Biopsy specimens obtained with a cystoscopic rongeur forceps may be helpful. If the specimen obtained definitely shows carcinoma the diagnosis is of course established. However a negative finding does not definitely exclude carcinoma. If there is any doubt it is well to withhold the further use of radium and keep the patient under careful cystoscopic observation for a few months. The appearance of a radium burn will remain about the same whereas a neoplasm will show a gradual extension and growth.

Treatment—There is no specific treatment. The condition is very obstinate and may persist for months or years. In the meantime the bladder should be kept as clean as possible by frequent lavage with some bland solution. This is done in part for the purpose of relieving the symptoms and in part to prevent the formation of calculi resulting from the precipitation of urinary salts on the ulcer base. Cystoscopy should be performed at fairly frequent intervals in order to determine the progress of the case and the presence of complications such as calculi or recurrence of the neoplasm. Occasionally it may be necessary to perform a suprapubic cystotomy for the purpose of putting the bladder at rest and obtaining large biopsy specimens in doubtful cases. On the whole they are extremely obstinate and difficult cases to handle.

Elusive Ulcer—Elusive ulcer which was first described by Hunner is a very definite pathologic and clinical entity. While its exact nature has not been demonstrated it

is generally supposed to be a metastatic streptococcus invasion of the submucosa of the bladder with resulting round cell infiltration and fibrosis. While there may be only a very tiny area of superficial ulceration this will often be surrounded by an extensive induration and marked thickening of the entire vesical wall. These areas may be single or multiple. The ulcers will often heal over temporarily only to break out in another place. The vast majority of these lesions occur in women.

Symptoms—The symptoms consist of marked frequency both by day and by night and severe pain referred to the suprapubic area and urethra markedly increased by even slight distention of the bladder. The patient may for one reason or another (drugs) sleep soundly for a few hours and be awakened by very severe pain which will be partly relieved by urination. Dysuria is not ordinarily a symptom. On the contrary, voiding often gives some relief.

Diagnosis—It is not always easy to make the diagnosis. When seen cystoscopically the ulcer appears as a tiny red spot surrounded by an area of congestion with dilated vessels. By careful observation rigidity and lack of pliability of the vesical wall will be noted. These findings may be observed at the first cystoscopic examination. Often however the condition is missed at the first examination only to be revealed later hence the term elusive ulcer. Repeated cystoscopic examination may show the lesion at one time in a certain area and at a later examination it may be healed and a similar lesion noted in another part of the bladder. The urine is usually crystal clear may show no abnormal elements under the microscope and may be sterile to ordinary cultural methods. However repeated careful examinations will usually show a few red blood cells and careful cultures may reveal a short chain streptococcus.

Treatment—This disease is extremely obstinate and may be wholly intractable to any form of treatment. One should hunt carefully for possible remote foci of infection and remove them. The writer has seen one case apparently cured following the removal of an infected tooth and tonsils. Short chain streptococci were demonstrated in the urine and also in the tooth and tonsils removed.

Santal oil administered internally occasionally affords some slight measure of relief. The writer has in a few cases obtained very definite results from the intravenous use of neoarsphenamine. Temporary relief sometimes lasting for weeks or months will occasionally follow forcible dilation of the bladder or light fulguration of the ulcer under anesthesia preferably spinal. Hunner has noted that these cases are frequently associated with bilateral ureteral strictures and that relief is often afforded by dilation of the strictures. Wide resection of the ulcer bearing area always affords relief for a time. However this operation which is one of considerable magnitude is rarely if ever justified since recurrence almost invariably occurs. In a few of the most severe and obstinate cases which have resisted all other forms of treatment if the patient's general condition warrants such a formidable procedure one may consider total cystectomy with transplantation of the ureters into the bowel.

There is a great temptation in all of these cases to resort to the use of opiates but the greatest care should be exercised since the patient will require increasingly larger doses and a habit is quickly formed.

DIVERTICULA OF THE URINARY BLADDER

Two types of out pouching of the bladder occur *sacculi* and *diverticula* differing not only in size but in clinical significance. *Sacculi* are present in every case of high grade obstruction of the lower portion of the urinary tract are smaller than the tip of the adult finger (1 cm. in depth) and recede when the obstructing agent is removed. *Diverticula* are larger in size and often re-

quire surgical treatment Vesical diverticulum is almost exclusively a disease of males It is occasionally encountered in boys and young men but nearly all of the cases occur in men over 40 years predominantly after 60 years, the age when obstruction is common

A diverticulum of the bladder like all hernias or diverticula in other organs occurs as a result of increased intravisceral tension or of weakness of the wall or both In nearly

and adhesions anchor the sac firmly to the surrounding tissues of the pelvis

The fundamental defect in diverticula is the absence of muscle in the wall weakness of vesical muscle is an essential predisposing factor and what contractile elements remain are so dispersed as to be functionally ineffective Since diverticula do not contract high grades of stasis often occur because of their presence leading to retention of crystals, with stone formation or, when infected

Fig 653.—Treatment of diverticulum of the bladder a The bladder has been opened and the diverticulum is being packed with gauze The shaded area represents the extent of the diverticulum which contains a stone b excision of the diverticulum from the outer surface of the bladder c closure of the bladder wall from the outside

every case vesical diverticulum occurs only as a result of urinary obstruction and thus is a *secondary lesion*

Surgical Pathology.—While vesical diverticula may form in any part of the bladder, nearly all of them originate at the junction of the trigone and the detrusor, the classical site is lateral to the urethral meatus, while occasionally the ureter itself opens into the sac It is usually bilaterally symmetrical A diverticulum often grows to a size considerably larger than that of the bladder itself developing on its postero-lateral aspect deep in the pelvis occasionally it lodges and becomes irreducible in the sac of an inguinal hernia Very often the diverticulum is loosely attached to the surrounding tissues so that it may be enucleated by blunt dissection less often peridiverticulitis

to putrefaction of the urine

Clinical Picture.—The vesical diverticula result in retention in the sac and therefore in the bladder A diverticulum as such produces no symptoms, its effects are manifested in protracted cystitis or in difficulty in emptying the bladder It should be suspected in any male with pyuria and vesical retention Most patients with vesical diverticulum as a result of prostatic obstruction are found on rectal examination to have a prostate which is small or only moderately enlarged (median bar formation), the prostatic hypertrophy may be large but this is less usual

Often the presence of a diverticulum is first suspected after an unsuccessful prostatectomy, if suprapubic prostatectomy has been done the incision will fail to close if

transurethral prostatectomy was performed the patient may be unable to urinate. When a diverticulum is irreducible in inguinal hernia the patient must manually compress the scrotum to urinate.

Putrefaction of urine in a diverticulum is one of the three causes of a nauseatingly foul smelling urine (the others being pyonephrosis and vesicocolic fistula).

Diagnosis—To be forewarned is to be forearmed is never more true than in the treatment of obstruction due to prostatic causes with reference to diverticulum. The urologist must always have diverticulum in mind when studying patients with prostatic obstruction if it should be overlooked the prostatectomy is apt to be a failure. It should also be thought of in the presence of pyuria with vesical retention in the male.

The diagnosis is made by two methods: cystoscopy and the cystogram. At cystoscopy a glistening dark cavern is seen in the region of the ureter or lateral to it. A cystogram is a roentgenogram taken after filling the bladder with a contrast medium such as 5 per cent solution of diodrast or sodium iodide. Sodium iodide is an electrolyte is irritating and must be evacuated after the x-ray is taken. A cystogram taken with the patient in a lateral position is often of help in making a diagnosis. The interpretation of cystograms is sometimes puzzling when the diverticulum is large and one is faced with the dilemma—*which sac is bladder and which is diverticulum?* The problem is easily solved by remembering that a diverticulum containing no muscle must have a smooth outline contrawise the bladder being obstructed is irregular in outline from sacculi. A further x-ray sign is the presence of laminated urinary calculi in the bladder region with absence of stones in the bladder at cystoscopy they may well lie in a diverticulum.

Treatment—In a minority of cases the diverticulum recedes spontaneously and spectacularly when lower urinary obstruction is removed by open or transurethral prostatectomy. Most diverticula however must be removed surgically. An unequivocal indication for operation is the presence of residual urine after the obstruction has been removed although usually it is not wise to delay the excision to this point. Practically it is best to excise a large diverticulum when

drainage is not dependent proceeding at a subsequent operation with suprapubic prostatectomy when the diverticulum is small transurethral prostatectomy may well be done with diverticulectomy later if residual urine persists. Enlargement of the mouth of a diverticulum by transurethral resection is not often followed by good results.

Technically a diverticulum is approached through a midline suprapubic incision after distention of the bladder with fluid it is unnecessary to open the peritoneal cavity. The sac is mobilized as much as possible extravesically before the bladder is opened. The orifice of the diverticulum is exposed and the neck of the sac is then transected and closed with sutures of catgut the fundus of the sac is then removed. At times it is helpful to open the bladder and insert a finger in the diverticulum to define its limits more accurately also the sac may be packed with gauze to make it more solid. A soft rubber drain is placed extravasically to avoid a burrowing abscess. In the rare instances where a ureter opens into the diverticulum it must be reimplanted in a new place in the bladder—the *ureterocystoneostomy* of Albarra.

A small diverticulum may be approached through the open bladder inverted by attaching a forceps to the wall of the fundus of the sac amputated and sutured transvesically. Operations on vesical diverticula give gratifying results.

CALCULI OF THE KIDNEY AND URETER, STRICTURES AND KINKS OF THE URETER

CALCULI

Calculus, *stone* and *gravel* are the terms applied to deposits of crystalline substance in the upper urinary tract. *Urinary calculi* are of two main types: (1) those formed in alkaline urine (phosphate and carbonate stones) and (2) those formed in acid urine

(uric acid urate cystine and the rare xanthine stones)

Stones may form at any age but the majority occur in patients under forty years of age. The writer has seen a small collection of shot like calculi in the kidney of a three week old baby removed at autopsy. In another case stones in the bladder left ureter and left kidney of an eighteen month old boy were removed by operation. The oldest patient suffering from renal calculi in the writer's series was eighty six years old and the proportion of males to females was approximately 3 to 2.

Etiology—Among the many etiological theories that have been advanced for the formation of urinary calculus are colloid crystalloid imbalance stasis infection vitamin A deficiency disturbance of calcium phosphorus metabolism due to hyperparathyroidism heredity racial predisposition and climate. Urinary stone rarely occurs in the absence of obstruction and infection. In recent years many cases of urinary calculi due to the administration of the sulfonamide drugs have been reported. Such calculi occur much more readily in an acid than in an alkaline urine.

Pathology—A kidney which harbors a calculus is always damaged thereby. Stone causes obstruction and this results in dilatation of the pelvis and calices and additional opportunity for the growth of bacteria with the accompanying toxicity which affects the patient generally as well as locally. Per sized calculi that become wedged in the ureter cause more general as well as local disturbance than larger calculi which remain in the kidney. Calculous anuria is rare. When it does occur it usually follows operation cystoscopy or other traumatism and is often fatal.

Symptomatology—Pain is usually the symptom which causes the patient to seek medical aid. This may be a dull ache in the affected loin but more often is colicky in nature. The agonizing pain of acute renal colic can be controlled only by morphine or one of its derivatives. The discomfort attendant on obstruction due to calculus in the upper urinary tract depends on the location of the stone and the degree of blockage. Partial obstruction at the ureteropelvic junction will cause a more or less constant ache

in the back between the crest of the ilium and the costovertebral angle. If obstruction is complete there will be intense colic. The patient feels as though his loin were being compressed in a vise. If obstruction is low down in the right ureter the pain may often be mistaken for irritation of the appendix. Frequently the pain radiates downward into the testicle or labium on the affected side. Hematuria occurs often in severe renal and ureteral colic. Hematuria either microscopic or more often macroscopic occurs in almost every case of stone. This is not constant and may pass unnoticed for years. General debility and even uremia may occur in long standing extensive cases of renal calculi. These are late manifestations however and some very large calculi may exist for a long time without their appearance.

Diagnosis—Roentgenography is of the greatest assistance in the diagnosis of stone in the upper urinary tract. Approximately 10 per cent of the calculi usually acid in type do not show in a plain x ray. Urography by the retrograde and intravenous method then becomes of paramount importance in making the diagnosis of calculus by means of filling defects. When these methods fail it is often useful to pass a wax tipped catheter. If the tip becomes scratched the diagnosis may be positively made even if the presence of a calculus is not made out by other methods. Extraordinary shadows may often be confusing because of their proximity to the upper urinary tract. A pyelogram will usually indicate the true location of the confounding shadow. When the obstruction is on the right side high up in the ureter or at the ureteropelvic junction the symptoms may be mistaken for those of cholecystitis and when low down on the right side for those of appendicitis or in the female of oophoritis. Urography and careful examination of the urinary specimens will clarify the situation in most instances.

Prognosis—The outlook for a patient suffering from renal or ureteral calculus is on the whole favorable. Many stones pass unaided and the majority of the others will pass with a little assistance on the part of the urologist. Calculi of the upper urinary tract are looked on as being very painful but rarely fatal. The nature of the discomfort is such that it cannot be disregarded

It drives the patient to seek medical aid early and induces him to undergo any amount of necessary treatment to avoid a recurrence of the symptoms.

Treatment—Symptomatic—Two principles are involved in the successful treatment of renal and ureteral colic—sedatives and heat. The agony of a patient with renal colic causes such rigid contractions of the musculature of the entire body and such tight constriction of the affected viscus that the obstruction to the urinary outflow is increased and the back pressure becomes more

such a caliber that the stone will not meet with too much obstruction. This is accomplished by passing many bougies beside one another by means of the Dourmashkin bag or by the wye bulb method of Hunner. The author uses all of these methods on occasion but ordinarily prefers the multiple bougies. One may persist for weeks in an endeavor to have stones pass if the patient does not have unbearable uncontrollable pain for long periods of time. If fever and other evidences of toxic absorption develop or if the patient is intolerant to cystoscopic manipu-

Fig. 64

Fig. 65

Fig. 64.—Roentgenogram showing a double exposure with the x-ray tube shifted. The shadow shifted exactly with the catheter thus proving that there was a calculus present in the ureter. If there had been a discrepancy in the two shadows it would have indicated that the shadow was on a different plane from that of the ureter.

Fig. 65.—There was a filling defect in the medium at the site of the shadow shown in the previous figure. This calculus passed after dilation and was removed from the bladder with the rongeur designed by the author.

marked therefore morphine in $\frac{1}{4}$ grain doses is the drug of choice. If the discomfort is moderate codeine in 1 grain doses is advisable. If sedatives are not immediately available or are contraindicated great temporary relief will be obtained by putting the patient in a very hot bath. If the obstruction causes only backache a hot pad or hot water bottle applied to the affected loin will be comforting.

Non Operative Treatment—Small calculi may be induced to pass from the kidney through the ureter by dilating the ureter to

lation operative intervention may be necessary.

Dissolution of Calculi by Chemical Means

—The writer has been able to dissolve newly formed phosphatic calculi (usually post operative recurrences) in some instances by means of the following solution:

Magnesium oxide and iron	0.51 Gm
Citric acid 1 H ₂ O	3.2 Gm
Sterile distilled water to make	1000 cc
Boil the solution 1 hour then cool. Boil another hour and then cool. Make up to 1000 cc with sterile distilled water.	

If a nephrostomy tube is still in place through and through irrigation is employed otherwise the renal pelvis is usually irrigated through a no 5 F catheter and drained through a no 8 or 9 F catheter

Operative Treatment of Renal Calculi—Removal of calculi from the renal pelvis may be accomplished by means of *polarotomy* or *nephrotomy* if the stones are large or deeply disposed. The operation of choice is

Fig 636—A large stone is being removed from the pelvis of the kidney through a nephrotomy. The lower pole of the ribbon gut is held in place.

the following procedure developed by the author by means of animal experimentation

An incision is made from the costovertebral angle downward and outward about 2 cm below the costal margin. This is deepened through the subcutaneous tissue, superficial fascia, muscular layers and the deep fascia care being taken not to excise the lower branches of the twelfth subcostal or the iliohypogastric nerves. The costovertebral fascia may be incised. This will allow the twelfth rib to swing up making resection of a rib unnecessary in most instances. The incision into the kidney is usually made in either the upper or the lower pole preferably on the lateral convex border. Almost any stone can be removed through a polar incision and this type of wound is more easily repaired than a central cortical incision. Ribbon gut is fixed in

position by being passed through the fibrous capsule on the anterior and posterior surfaces. An incision is made into the cortex between the two capsular straps. The calculus is located and removed. A drainage tube is inserted through the wound into the pelvis. A piece of fat is placed in the wound for hemostasis and the ends of the ribbon gut are tied over it with just enough pressure to approximate the wound edges. The kidney is replaced in its bed. Penrose drains are placed down to the nephrostomy and the wound is closed. The nephrostomy tube is held in place at the posterior angle of the wound by a suture passed through the ribbon gut.

Resection of a dependent or constricted calyx is sometimes indicated in order to prevent recurrence following removal of a stone since such calyces are especially favorable media for stone formation.

Fig 637—The ribbon gut is placed with the knot tied away from the wound in the kidney. A small piece of fat is sutured on the surface of the incision through the cortex of the kidney. A tube is placed in the pelvis and fixed in position by a catgut strand passed through the edge of the ribbon gut.

Operative Treatment of Ureteral Calculi—An incision is made in the nipple line extending from a point just below the costal margin down to a point in front of the anterior superior spine of the ilium. If the calculus is in the lower end of the ureter the inferior portion of the incision is turned toward the midline across the rectus muscle which with its sheath may be divided partly or entirely across. This incision is deepened through the superficial fascia, muscular

layers and deep fascia and the peritoneum is carefully separated from the skeletal wall. The latter and its contents are pulled to ward the midline with large retractors protected by abdominal pads. The ureter is identified best as it crosses the bifurcation of the iliac vessels. It is isolated from the peritoneum to which it clings tightly in this area and followed to the point at which the stone rests. It is well to milk the calculus up to a point above its resting place because there is always a constriction at the point of impaction with a dilatation above it. The ureter is incised and the calculus is grasped with special forceps and removed. A flexible probe is inserted into the ureter to dilate it. A single catgut suture passed through the wall of the ureter but not into its lumen closes the incision. The wound is closed in layers with ample Penrose drains. Catgut is used for the muscular and fascial repair and tension sutures for the skin.

After three or four days the drainage of urine through the wound stops and the drains may be removed. Dilation of the ureter after ureterotomy is absolutely necessary; otherwise a stricture will develop at the site of the incision because of the isolation of the ureter and incision into it, all of which is bathed in infected urine. There is no agency more potent in laying down scar tissue than infected urine; hence the necessity for postoperative dilation.

Prevention of Recurrence of Calculi.—Prevention of the recurrence of calculi is a most important part of the postoperative care and may be accomplished as follows:

1. Every possible obstruction to the urinary outflow should be eliminated.

2. Infection should be treated by ureteral and renal pelvic irrigations of urothymine 1:2000 or rivinol dextrose 1:2000 and by internal medication in the form of methenamine and acid sodium phosphate (in divided doses of 60 grains or more of the former daily and enough of the latter to keep the urine acid) or one of the sulfonamide drugs (10 to 20 grains three times a day and then less). Treatment with sulfonamides should not be continued indefinitely.

3. The retention of the urine should be changed. If acid calculi have been removed the urine should be kept slightly alkaline and vice versa. To this end alkaline ash

diets and acid ash diets are utilized. If the alkaline diet is not effective the patient should be given sodium bicarbonate or sodasun by mouth and urged to take alkaline waters, a very good domestic one being Karik water. If acidification is desired sodium benzoate and sodium phosphate or ammonium chloride may be found helpful in addition to the acid ash diet. It is advisable to augment both the acid ash and the alkaline ash diet with the administration of vitamin A in the form of haliver oil capsules, carotene in oil etc.

STRICTURE OF THE URETER

Etiology.—Stricture of the ureter may be congenital or acquired. Congenital strictures are usually exaggerations of the normal anatomical points of narrowing in the ureter without infection. Acquired strictures are caused by infection either within or outside the viscus. Munter claims that metastatic infection may originate in the tonsils and be deposited in the wall of the ureter resulting in narrowing. The tubercle bacillus is responsible for stricture of the ureter in most cases of long standing. Chronic irritation and the resulting inflammatory reaction result in the laying down of fibrous tissue and the lumen of the ureter gradually becomes occluded. Another source of ureteral occlusion or semi occlusion is inflammatory reaction around the ureter due to disease in a neighboring structure usually a lymph gland. The intramural portion of the ureter is often narrowed as a result of chronic cystitis. Stricture may follow ureterotomy for stone. The ureter in such an operation is isolated and incised, allowing it to be surrounded for a considerable time by infected urine and producing an intense inflammatory reaction.

Stricture of the ureter occurs frequently but it is not so common as some enthusiasts would have us believe.

Symptoms.—These vary in intensity from slight frequency of urination and dull backache to the most intense renal colic.

Diagnosis.—Diagnosis is made by two methods. The most useful in the author's hands is the pyeloureterogram accomplished by injecting a non irritating non toxic opaque substance such as neo iopax into the suspected side by means of a ure-

teral catheter and taking a roentgenogram preferably with the patient in an erect or semi-erect posture. Serial pyelograms are especially useful (The intravenous urogram is also satisfactory.) The other method consists of passing a catheter with a wax bulb into the ureter and observing the so-called ureteral hang when the bulb engages in the narrowed part of the ureter. Confusion of stricture with stone in the ureter which may give identical symptoms is usually avoided by the fact that the stone is often demonstrable in a roentgenogram.

Prognosis—This depends largely on the etiology of the stricture. A narrowing caused by the tubercle bacillus is best treated by removing the kidney above it provided the other kidney is competent. On the whole the outlook for a patient suffering from stricture of the ureter is favorable and the discomfort will often be relieved by the mere passing of a No. 6 F catheter for the purpose of examination.

Treatment—Symptomatic treatment consists of internal medication to relieve the burning urination which often occurs. In a mild case the patient may be given the following every four hours with great relief:

Tincture hyoscyamus	℥j
Potassium citrate	℥j
Water	3vj

Sig.—j every four hours in water

In cases of severe pain in the back cocaine in $\frac{1}{4}$ or 1 grain doses may be required and in severe renal colic morphine should be given hypodermically. Hot applications and very hot baths often are comforting.

Cystoscopic treatment is the most important therapeutic measure in the care of a patient suffering from stricture. Dilatation of the narrowed duct is best accomplished by passing bougies of increasing sizes. Bougies may also be passed simultaneously so that two or even three are utilized to enlarge the lumen to a diameter corresponding to that of a No. 23 or 24 F catheter.

Operative measures are often important in the treatment of stricture. Such procedures usually are necessary at the ureteropelvic junction and consist in the removal of any extraneous influences such as aberrant vessels or adhesive bands and various

plastic operations. The two that the writer has found most useful are the Foley's plasty and ureteropelvicostomy (reimplantation of the ureter into the most dependent portion of the pelvis after resection of the strictured area). Prolonged nephrostomy drainage and ureteral splinting (six weeks) are of prime importance in ureteropelvic surgery.

KINKS OF THE URETER

Etiology—There are two causes for kinks in the ureter. The more common is *nephroptosis*. The other less common is

FIG. 63.—This pyelogram shows a kink and stricture of the right ureter with slight hydronephrosis above it. The patient had had two major operations for the relief of the accompanying right-sided pain and was about to have another one. Elevation of the kidney by means of a belt and dilatation of the ureter effected a cure.

hydroureter due to obstruction of long standing at the lower end of the ureter or even at the vesical outlet.

Pathology—The ureter is always enlarged above the site of the kink and there is usually considerable narrowing of the ureter at this point.

Symptoms—There is always pain in the back on the affected side. Occasionally colic

may be intense and there is usually urinary frequency

Prognosis.—When the kink is due to nephroptosis proper treatment of this condition will almost invariably bring relief unless there is also entropsis in which case the outlook is not good. When the condition is secondary to lower ureteral or bladder neck obstruction ureteral dilation will usually prove satisfactory unless the dilation and elongation causing the kinking are considerable or the loops are matted together.

Treatment.—*Symptomatic Treatment.*—Symptomatic treatment is accomplished by various means designed to restore the ptosed kidney to its normal position. When the kidney is in its proper place the ureter will straighten out and the kink will be relieved allowing proper drainage. The simplest method of accomplishing this is to apply a properly fitted belt supplied with a pad or pads for exerting pressure on the lower pole of the kidney and restoring it to its proper place. This belt should be applied with the patient lying on the back and should be tightened from below upward. At night the patient should sleep with the foot of the bed elevated. In severe cases the pain must be relieved by sedatives.

Cystoscopic Treatment.—The strictures resulting from longstanding kinks of the ureter must be dilated with bougies.

Operative Treatment.—Nephropexy or sewing up of the kidney is sometimes necessary to reduce nephroptosis. This may be accomplished by the author's ribbon gut suspension method.

TUMORS AND CYSTS OF THE KIDNEY AND URETER

New growths of the kidney are fairly common but nevertheless of great importance because they are very deadly and but the only hope for improvement in the results of treatment lies in early diagnosis. Malignant tumors of the kidney constitute about 0.3 per cent of all urological and about the same percentage of all renal tumors in adults. While malignant tumors are much rarer in children yet first decide the kidney furnishes cancer every five and more than any other organ of the body.

Pathology.—*Neoplasms.*—HISTIOLOGY.—Hypernephroma (nephroma) Wilms tumor angiosarcoma endothelial clear cell epithelioma perithelial angiosarcoma) is the commonest tumor of the kidney. It is usually called a hypernephroma because it resembles microscopically the renal tissue of the adrenal gland. There is no definite proof however that it is from misplaced bits of adrenal tissue. A tumor may arise in any part of the cortex a little more frequently in the pole. It is enclosed by a capsule so that it does not invade the renal tissue but it grows inside and causes pressure absorption. It does tend to invade the renal pelvis forming small or large processes into it and sometimes filling it completely. It may also invade the renal vein sending processes into it which may extend to the ventricle and even the heart. Some believe the tumor to be benign in its early stages but it has possibilities of malignancy. In the early cut surface is opaque has a yellow tint and is varied by areas of necrosis, red or brown areas of hemorrhage and red spots due to blood filled cysts. The blood supply of the kidney is increased the capsular vessels may be dilated. Microscopically the typical cells have small nuclei and the cytoplasm is glandular distended by droplets of lipid material which appears clear and does not stain with ordinary stains. These cells usually occur in solid alveoli but the alveoli may be dilated and the cells often contain blood. They are sometimes distended into good sized cysts containing fresh or old blood.

PAPILLARY CYSTADENOMA—This tumor is also encapsulated but is characterized by cyst like cavities filled by enormous numbers of fine branching papillae. The cysts never communicate with the pelvis. The walls and papillae are covered with one layer of cuboidal epithelium.

CARCINOMA AND ADENOCARCINOMA—Some renal tumors are made up of cells which are grouped in alveoli but do not have the clear distended cytoplasm which is characteristic of hypernephroma. The alveoli may or may not have lumens if they have the tumor is called an adenocarcinoma. There may also be a failure of encapsulation with strands and cords of tumor cells invading the renal tissue. Such tumors are often called carcinoma of the kidney but this classification is indistinct and there is much dispute among pathologists as to what tumors should be assigned to it.

In fact little is known about the histogenesis of all these tumors and all three microscopic types may occasionally be found in a single tumor mass. They all have many gross characteristics in common the most important of which is invasion of the renal pelvis causing the filling defects which are demonstrated by means of pyelography.

Cortical renal tumors usually metastasize first to the lungs sometimes to the suprarenal gland later to any organ of the body. The metastases may be quite unlike the primary tumor histologically.

SARCOMA—Sarcoma of the kidney is rare. It may arise in the kidney or in the neighboring retroperitoneal tissue. There is no capsule and the renal tissue is freely invaded in all directions so that there is no characteristic pelvic deformity. Other tissues and organs also may be invaded and bound into one mass with the kidney. Rarely lymphosarcoma may invade the kidney. The growth characteristics of sarcoma make successful surgical treatment almost impossible.

EMBRYOMA—The embryomas include Wilms mixed tumor leiomyosarcoma rhabdomyosarcoma myxosarcoma chondrosarcoma adenosarcoma teratoma dermoid etc. Most of the tumors of the kidney which occur in infants are embryomatous but embryomas

occasionally occur in adults. These tumors may arise in the kidney itself in the connective tissue of the hilus or in the perirenal tissues. They may compress the kidney from the outside or may expand it by growing from within. In the gross they are usually found to be smooth and not adherent to the surrounding organs but their attachments in the retroperitoneal tissues are often very extensive making surgical removal difficult. Hemorrhage and necrosis are rare. Metastases do not occur unless carcinomatous or sarcomatous degeneration has taken place which happens in from 20 to 35 per cent of cases. The tumors nevertheless may cause death from local recurrence after surgical removal. The rate of growth often shows a sudden dramatic increase. As there is no tendency to intrapelvic growth there is no characteristic pelvic deformity and hematuria is rare though it may occur. Microscopically there is usually an abundant connective tissue stroma of embryonic type beset with renal or tubules lined with epithelium. The stroma may be myxomatous (gelatinous). Frequently completely differentiated tissues are found such as smooth and striated muscle cartilage intestinal mucosa etc. Rarely there is an actual dermoid cyst with skin hair teeth etc.

PAPILLOMA OF THE RENAL PELVIS AND URETER—The epithelium of the renal pelvis and ureter is exactly like that of the bladder so that papillary tumors may arise which are exactly like papillomas of the bladder. These grow in villous and branching in character are benign and form masses projecting into the lumen of the pelvis or of the ureter. They may be single or multiple sometimes with hundreds of separate tumors. Multiple tumors are more apt to be malignant. Implantation may occur to any point in the ureter or bladder below the original tumor therefore papilloma of the pelvis must be suspected in every case of papilloma of the bladder.

PAPILLARY CARCINOMA OF THE RENAL PELVIS AND URETER—Like papilloma of the bladder papilloma of the kidney pelvis may take on malignant characteristics. The malignant cells invade the renal tissue so that in the later stages the pelvic origin may not be apparent. Necrosis and ulceration may develop and adjacent organs may be in-

vaded Metastasis may occur to any organ as in carcinoma of the bladder

LITHIOMIA OF THE RENAL PELVIS AND URETER—Epithelioma must be preceded by metaplasia (leukoplakia) of the renal or ureteral epithelium which is usually caused by chronic infection sometimes by calculi. The epithelioma may be either basal cell or squamous cell. Like all others of its type it invades all tissues indiscriminately and ulcerates early. It may obstruct the ureter causing hydronephrosis. There is no characteristic pelvic deformity. Metastasis is fairly late and may occur to any organ. This tumor is practically never diagnosed in time for effective treatment.

ANGIOMA OF THE KIDNEY—Hemangiomas are usually small. They may lie in any part of the kidney and give no symptoms unless they are in contact with the pelvic mucosa when they may occasion severe hemorrhage out of proportion to their size.

METASTATIC TUMORS OF THE KIDNEY AND URETER—Metastases in the kidney are rare, perhaps offshoots from tumors of the opposite kidney, next from tumors of the uterus and less frequently from tumors of the prostate, stomach and breast. Severe perirenal hemorrhage may occur. Metastases to the ureter are even rarer. When present they are usually from tumors of the bladder or prostate and always cause obstruction and hydronephrosis.

Cysts—**SIMPLE CYST OF THE KIDNEY** (*Serosa Cyst Solitary Cyst*)—A simple cyst is not a neoplasm but may cause great enlargement in the region of the kidney. The condition is comparatively uncommon. The cyst occurs a little more frequently at the lower pole than at the upper or in the midportion. There is no fibrous capsule; the cyst lies in direct contact with the perinephrium and is lined with a thin simple layer of epithelium. The contents are clear and transparent and may contain an excess of urea like urine. The pathogenesis is unknown. The cysts vary in size from those which are a few millimeters in diameter to those which can hold as much as 10 liters.

HEMORRHAGIC CYST OF THE KIDNEY—Sometimes the contents of a renal cyst are bloody. Excluding blood containing cystic spaces in malignant tumors there are three

theories for the development of a hemorrhagic cyst: (1) an entity of unknown pathogenesis; (2) arising from an aneurysm of an intrarenal artery; and (3) hemorrhage from the erosion of a blood vessel into a serous cyst.

EXTRARENAL CYSTS—Occasionally extrarenal cysts, some of them very large, are seen. They are thought to result from traumatism and probably follow reorption of hematomas. The walls are composed of fibrous tissue often with heavy deposits of calcareous material so that the outline can be clearly seen in roentgenograms.

POLYCYSTIC KIDNEYS—Polycystic kidneys are congenital and always bilateral. The kidneys contain large numbers of thin walled cysts thought to be the result of obstruction of the renal tubules or of occlusion following their failure to unite with the collecting tubules in embryo. The cysts gradually increase in size causing ischemia and absorption of the normal renal tissue between them so that death from renal insufficiency usually occurs at about the age of fifty. The pelvis is distorted and elongated.

Miscellaneous—**ANEURYSM OF THE RENAL ARTERY**—This is a rare condition which is usually indistinguishable clinically from a tumor of the kidney causing mass pain and hematuria. It may be a true aneurysm or a false or dissecting aneurysm.

LECHINOCOCCUS CYST OF THE KIDNEY—Ichthococcus cyst (hydatid cyst) is a disease which may involve the kidney, sometimes a renal tumor. The cyst may rupture into the pelvis or into the peritoneum. Obstruction with hydronephrosis may be caused.

PERINEURAL SCLEROSIS—Following injury if there are both hematoma and infection large amounts of scar tissue may be deposited about the kidney causing severe late pain and sometimes a palpable mass.

DIVERTICULUM OF THE URETER—This condition is rare and usually follows injury. Large or small cavities develop which are filled with urine and communicate by a small opening with the ureter. The cavity may grow very large and acquire a fibrous wall.

Symptoms—The three cardinal symptoms of renal neoplasm are hematuria, mass and pain. Yet it is true that pain is often

a late symptom and that by the time a palpable mass develops it is in most cases too late for successful treatment. Hematuria therefore particularly if without pain frequency of urination or any other symptom is the most important danger signal and its source should always be determined by thorough examination at the earliest possible moment. The examination should not be delayed if the bleeding stops as weeks or months may elapse before blood again ap-

pears. Hematuria is unusual occurring in 10 per cent or less of the cases.

Renal cysts usually cause no symptoms except a mass in the region of the kidney occasionally there is pain.

Tumors of the ureter usually cause hematuria. Obstruction is common giving rise to renal colic and hydronephrotic enlargement of the kidney.

Hematuria is a common symptom of polycystic kidney. The kidneys can usually be

Fig 659

Fig 660

Fig 659—Roentgenogram of man aged thirty five hematuria and pain in left kidney diagnosis of renal neoplasm possibly papilloma of the pelvis so the entire ureter was removed with the kidney diagnosis confirmed preoperatively radiation on patient as all three years after operation.

pears. Unfortunately there are a good many cases in which no symptom appears until the growth is far advanced.

Pressure on the spermatic veins by the tumor may cause hemolateral varicocele in the male. Edema of the legs and ascites may occur.

In the embryonal neoplasms of children an abdominal mass is usually the first symptom and pain does not ordinarily begin until

felt. In the later stages pain is common and finally the symptoms of uremia appear.

Diagnosis—General—The diagnostic study includes seven steps some of which may be omitted in some cases: (1) history (2) physical examination (3) examination of the urine (4) intravenous urography (5) ureteral meatoscopy (6) functional study of the two kidneys and (7) retrograde pyeloureterography. The first four of these

can be undertaken by any physician and will very frequently establish the diagnosis.

The history should particularly include the duration and the character of hematuria and of pain if present and also the number of attacks of each.

A careful physical examination must be made to disclose palpable renal tumor and secondary effects such as ascites, edema, varicocele and dilated veins and also to detect metastases especially in the cervical glands. If the function of one kidney is destroyed by a tumor the other will also be enlarged as the result of compensatory hypertrophy.

The urine is examined for microscopic blood. If pus is present stone or tuberculous is suspected; if these are ruled out neoplasm is more likely. Sometimes tumor cells or fragments may be identified. Casts and much albumin make one think of the possibility of acute or subacute nephritis as the cause of blood in the urine.

Intravenous Urogram—A plain film should be taken first to exclude stone. Intravenous urography is useless for the early diagnosis of renal tumor as both false positive and false negative findings are frequent. If a kidney is functionless there will be no shadow whatever.

If a renal neoplasm is seriously suspected cystoscopic examination should be carried out. If hematuria is present inspection of the ureteral orifices (metoscopes) will show from which side the blood is coming.

Ureteral catheters are then passed to both kidneys and urine is collected. If the urine is bloody from both kidneys the condition is probably a nephritis. A comparative functional test preferably with phenolsulfonphthalein will show how much the function of the affected kidney is damaged and also whether the other kidney has assumed its extra work properly.

A retrograde pyelogram is then taken enough 12 to 18 per cent solution of skiodin or iopax being injected to fill the pelvis. The catheter is partially withdrawn to allow the ureter to fill. Stereoscopic films are best.

The characteristic picture is due to a tumor mass which projects into the pelvis and one looks therefore for a rounded filling defect with the convexity toward the hilum since the tumor springs from the paren-

chyma. Sometimes the pelvis is almost or entirely obliterated by a large tumor or by blood clots in the pelvis. The projecting mass may obliterate one or more minor calices. The kidney may be pushed out of its normal position by the tumor. A tumor in the lower pole may increase the distance between the ureter and the lowermost portion of the pelvis. Renal cysts may obliterate part of the pelvis and displace the kidney but they never cause the typical rounded filling defects of a tumor. Teratoma, sarcoma and epithelioma deform the pelvis sometimes extensively but according to no rule and are therefore very difficult to diagnose. Polycystic kidney has an elongated pelvis with elongated spider-like calices and often numerous round filling defects due to the cysts. It always involves both kidneys sometimes one being much more deformed than the other. Ureteral neoplasms may cause filling defects in the ureter which are often very difficult to bring out satisfactorily. Study of the renal outline may show irregularity due to tumor.

These same steps should be taken in children as cystoscopic examination is now possible in the youngest infants. While embryomas give no characteristic pyelogram marked distortion proves the renal origin of the tumor and in addition the other kidney can be properly studied.

The pyelogram will establish the diagnosis in most cases or at least in from 70 to 75 per cent. If the diagnosis is not certain and particularly if an enlarged kidney can be felt it is better to explore as time is a tremendously important factor. Weeks, months or even years may be wasted waiting for a positive pyelogram.

If the aforementioned plan is followed the differential diagnosis seldom presents difficulties. Carbuncle of the kidney and perinephric abscess may simulate a tumor of the kidney but are characterized by fever and leukocytosis. Hydronephrosis is apparent but it must be remembered that it may accompany a tumor.

If a neoplasm is suspected any nodules in the skin or large glands should be studied by biopsy and a roentgenogram of the chest should be made. If any pulmonary metastases are found nothing can be done except administer palliative treatment.

Treatment—There is only one treatment for renal neoplasm nephrectomy performed as early as possible. Unless removal of the tumor is complete there is no hope of cure. Before operating one must make sure that the other kidney is healthy and able to maintain life. The approach is usually extraperitoneal and lumbar but the transperitoneal route may be preferable for a very large tumor. An effort should be made to ligate the pedicle before disturbing the tumor. If a lumbar incision is used it is extended straight across the abdomen to the edge of the rectus muscle giving access to the pedicle. Resection of the twelfth rib is advisable in large tumors. In transperitoneal operations the pedicle should be sought first. The ureter is crushed, ligated and divided with the enteric. The kidney should be opened as soon as it has been removed and if a papilloma of the pelvis is found complete ureterectomy including a button of bladder wall must follow to eradicate any possible implants in the ureter.

Intensive roentgen therapy has produced no cure in tumor of the kidney but is often very useful in reducing the size of a tumor preliminary to operation. Tumors so large as to be inoperable should always be irradiated as they may be reduced sufficiently to become operable. These tumors are not suitable for radium treatment.

Limbomias must be removed if possible but may recur locally. Ladd has an excellent series of long term cures (23 per cent) after early and very radical surgical removal (transperitoneal). Postoperative irradiation is of doubtful value.

Renal cysts are treated by removal of that portion of the kidney which bears the cyst unless more than a third of the kidney is involved. In that case nephrectomy is performed.

There is no treatment for polycystic kidney unless complicated by stone hydro-nephrosis or infection in which case the usual treatment for these conditions is given. Hemorrhage may be arrested by pelvic lavage with silver nitrate or epinephrine. Operative puncture of the cysts (Rossing's operation) has given unsatisfactory results.

Aneurysm of the renal artery is treated by nephrectomy with ligation of the artery proximal to the aneurysm.

Tumors of the ureter are treated by complete nephroureterectomy.

In cases of inoperable tumor pain and hemorrhage must be combated. Pain is often due to bleeding with clots. Pelvic lavage with silver nitrate or epinephrine may stop the bleeding. Transfusion is useful. If all else fails ligation of the ureter is usually successful.

Prognosis—Any kind of renal neoplasm is almost invariably fatal if not treated. In about one third of all cases in which the patient applies for treatment the tumor is inoperable. Of the cases which are considered operable there will be some in which complete removal of the tumor is not possible. These patients will die. If removal is apparently complete and if metastases do not develop there may be recurrence at any time up to ten or twelve years later. The number of permanent cures is distressingly low not over 10 or 15 per cent. In the others metastases will finally become evident but they were undoubtedly present but not demonstrable before operation. The operative mortality varies in different series from 4 to 31 per cent. Generally speaking the results are better when operation is performed soon after the appearance of symptoms but there are rather numerous exceptions to this rule.

The results of benign papilloma of the pelvis are much better than this if the ureter is completely removed. In most of these cases a cure is obtained.

Limbomias in children are very fatal but recurrences are rare after two years. Ladd's work offers great hope for improvement in results after operation.

Sarcoma and epithelioma are practically always fatal.

An angioma is harmless unless it ruptures into the pelvis causing hemorrhage. Nephrectomy is curative and operative death rarely occurs.

In simple cyst of the kidney there is no mortality except the operative which depends largely on the skill of the surgeon.

Patients with polycystic kidneys practically never live to be more than fifty years old. Very little can be done to prolong life except by treating intercurrent disease due to stone infection obstruction etc.

Tumors of the ureter are difficult to diag-

nose and therefore are more apt to be treated unsuccessfully than tumors of the kidney. No accurate figures as to results are available.

TUMORS OF THE BLADDER

Historical.—In the early part of the last century the cystoscope was being developed in Berlin and Vienna. Prior to this tumors of the bladder had been recognized both at autopsy and at operation. The peculiarities of papilloma of the bladder were known, i. e., (1) they do not invade the bladder; they do not metastasize; they are multiple and they tend to recur after surgical removal. Nitze in Berlin was the first to recognize and treat them seriously through the cystoscope. He used a wire loop heated electrically, red hot, snared the tumors with this, burned them off and had the patient pass the burned off portions on urination. He published in 1876 a report of a large series of cases of papillomas so treated. Because of the large size of the instrument and the difficulty of the procedure, no other surgeon to my knowledge ever used it extensively. Even with this noteworthy achievement by Nitze, surgeons were everywhere very reluctant to accept his teachings. Not until Beer in New York in 1910 used a simpler device of high frequency current to destroy papillomas did the method come into its own. All urologists used it both for papilloma and for carcinoma in the former with excellent results and in the latter disastrously. Because of its impotence in carcinoma, surgical excision of these tumors was developed. Beer, Geraghty, Young, Squires, the Mayors, Lower, Albarran and others began to use it. But the removal of these tumors is difficult surgically because most of them arise in the base of the bladder near

the ureters, hence at first the surgical results were not brilliant. Because of this the author started the radium treatment of these tumors in 1915. Various forms of radium application were used but the most trustworthy were the ones developed by the author of both cystoscopic and suprapubic implantation of radium seeds. The first suprapubic implantation was done in 1920 at the Memorial Hospital in New York. The caustic glass seeds were originally used and finally gold seeds which filter out the caustic beta rays. Urologists were slow to take up this method because of the difficulty of getting radium in proper form. Young, Geraghty, Kelli and Barnum developed other forms of radium technique particularly the endovesical application. Finally deep x-ray therapy was extensively tried out and likewise surgical diathermy.

Etiology.—Little is known of the cause of tumors of the bladder but it is recognized that the workers in aniline dye factories are subject to them. They may arise years after the workers leave the factory. Yet the urine of these workers does not differ at all chemically or otherwise from the urine of persons outside the dye factories.

Most of the tumors start in the base of the bladder around the trigone. This is the region which is most often the site of cystitis caused by infected urine from the kidneys or infection by way of the urethra (gonorrhea). This suggests that infection and irritation may be a factor in the cause of vesical tumors but certainly it is only one of several factors.

Pathology.—Tumors of the bladder are classified as follows:

Primary tumors

A From epithelial tissue

- 1 Papilloma
- 2 Papillary carcinoma
- 3 Infiltrating (non papillary) carcinoma
 - a Simple carcinomatous ulcer
 - b Flat squamous cell carcinoma
- 4 Adenocarcinoma

Generally secondary to a tumor of the prostate but very rarely primary and if so originating in Brunner's glands.

- 5 Colloid carcinoma
- From Brunner's glands (rare)

B From connective tissue

- 1 Fibroma
- 2 Myxoma
- 3 Sarcoma

C From muscle tissue

- Myoma

D Heterotopic forms

- 1 Chondroma
- 2 Rhabdomyoma
- 3 Dermoid

F Cysts

Tumors secondary to tumors in the following locations*

- A Prostate
 - 1 Fibrocarcinoma
 - 2 Adenocarcinoma
 - 3 Adenoma
 - 4 Fibroadenoma
 - 5 Sarcoma (young adults)
- B Seminal vesicles
 - Carcinoma
- C Intestinal tract
 - Glandular carcinoma
 - Adenocarcinoma
 - Mucous carcinoma
- D Cervix
 - Squamous carcinoma
 - Adenocarcinoma (rarely)
- E Vagina
 - Sarcoma (especially in children)

The first three types of tumors (papilloma, papillary carcinoma and infiltrating carcinoma) which arise from the epithelial lining of the bladder are by far the most important and will be considered in some detail.

As far as the secondary tumors of the bladder are concerned it is well to remember that tumors arising in organs adjacent to the bladder may grow from these organs into the bladder. Such tumors are of the same pathologic type as the primary tumor and can often be identified by this alone. This is particularly true of vesical tumors secondary to tumors of the prostate (adenocarcinoma) and intestines (glandular carcinoma).

The two most important sources of secondary vesical tumors are the prostate and the cervix.

Papilloma, Papillary Carcinoma and Infiltrating Carcinoma—From the clinician's standpoint and it is the clinician who is responsible for the diagnosis and treatment these three types of tumors must be identified grossly with reasonable accuracy. If microscopic examination of the entire tumor is possible and if the findings disagree with the clinical estimate then the clinical diagnosis must give way to the pathologic diagnosis. If however as is often the case only small portions of the tumor are available for the pathologic diagnosis then more weight is placed on the clinical picture. In other words vesical tumors sometimes vary in their structure and the pathologic examination of the top of a tumor may not reveal the real structure of the base.

A *papilloma* may be single or multiple and may arise from any portion of the interior of the bladder. As seen through the cystoscope it resembles delicate pink seaweed waving in the vesical fluid. Many pink tufts may spring from the pedicle which attaches it to the bladder. It is very rarely white or sloughy unless covered with phosphate deposited from the urine. If the tumor is white or sloughy the tumor is in all probability cancerous. Microscopically the pedicle is composed of connective tissue, unstriped muscle fibers, blood vessels, nerves and surface epithelium. The latter is continuous with the epithelium of the mucosa. In the villous portion of the tumor the epithelial elements as well as the connective tissue fibers combine to form the bulk of the growth.

The tendency for a papilloma to recur after its removal is a well established fact. The growth frequently reappears as a simple benign tumor though in some instances it may be distinctly malignant in character. At times several apparently benign papillomas may be found one of which may prove to be malignant. This fact however may not be known until a microscopic examination is made for the two forms closely resemble each other macroscopically. A tumor may show in one part the characteristics of a pure papilloma and in another part those of a carcinoma.

The cystoscopic picture of *papilloma* and *papillary carcinoma* may be identical hence the true diagnosis must rest on the pathologic examination. As a rule a papillary carcinoma is single, may be partly or entirely sloughy and generally looks firmer and harder than a papilloma. Mandelbaum says:

Histologically the picture of carcinoma in well advanced cases is typical. In earlier stages the epithelial cells lose the typical arrangement as seen in papilloma and are polymorphous in character; the nuclei become larger and more irregular; an atypical proliferation occurs and finally the infiltration of the stroma takes place. Proliferation of the bladder wall is very rare and metastases occur only in the late stages. The tumor in its later stages may infiltrate the wall of the bladder.

An *infiltrating carcinoma* is entirely different from either of the other tumors at

though the papillary tumor may become infiltrating. It usually begins as a flat ulcer which is difficult to differentiate except by means of the microscope from a simple or tuberculous ulcer. It is generally single and

the work of Broders an attempt is made by pathologists to grade all tumors in relation to their malignancy. Four grades were chosen by Broders grade 1 being the least malignant and grade 4 the most. This scheme has

Fig 661—Papilloma of the bladder (Model made from life by G. R. Richardson)

Fig 662—Papillary carcinoma of the bladder (A model made from life by G. R. Richardson)

sloughy. Its edges become thickened and raised and it rapidly infiltrates the vesical wall. It is the most malignant of all tumors of the bladder.

Grading of Tumors—In accordance with

proved to be valuable in the diagnosis of tumors of the bladder. In the bladder grade 1 has represented pure papilloma and grades 2, 3 and 4 have represented carcinoma. This gradation has been objected to by Wing

because he does not consider papillomas to be in the class with carcinoma. His gradation is papilloma and grades 1, 2 and 3 of carcinoma. If we accept the grade 4 classification, more tumors of the bladder are in grade 2 and the fewest in grade 4. There exists still another class of tumors of the bladder, called by Geraghty malignant papilloma and by pathologists papilloma with atypical cells, which we believe should be classified as grade 2 carcinoma. In finally classifying tumors of the bladder it is probable that the three original classes, viz., papilloma, papillary carcinoma and infiltrating carcinoma, are the most satisfactory

pathologist change later to a highly malignant, rapidly growing, infiltrating carcinoma.

Another phase of the question is the varying diagnoses of the pathologist of different specimens taken from the same patient. For example, in 19 of 46 cases at the Memorial Hospital there were pathologic variations in the diagnosis of different specimens. It is always wise to take several specimens in these cases if the growth is believed to be malignant yet pathologically the report is papilloma.

Incidence—Papilloma of the bladder may occur at any age between two and one-half and seventy-nine years. As a rule it occurs

Fig. 603—*a*, Simple papilloma of the bladder, low power, *b*, infiltrating squamous cell carcinoma of the bladder, low power. Both of these illustrations are from the Bladder Carcinoma Registry, Army Institute of Pathology, Washington, D. C., courtesy of Dr. Russell Ferguson.

The grades of malignancy may be used to modify the diagnosis in these three classes. The grading is of more value to the urologist who surgically removes the tumors than to the urologist who uses radium therapy. The grade 4 tumors constitute the worst operative risk.

Changes of the Grade of Malignancy—Some tumors of the bladder change their grade of malignancy, this, in our experience, being due to the trauma of imperfect operations or to operative devices such as fulguration and the like. We have seen a tumor which filled the entire bladder and was diagnosed as papilloma by a competent

at an earlier age than carcinoma. On the other hand, the age periods of the greatest frequency of these two overlap, that of papilloma being between forty and sixty, and that of carcinoma between fifty and seventy. Geraghty gives the age in 73 cases of papilloma as follows:

Age, in Years	Cases
10 to 20	1
21 to 30	5
31 to 40	15
41 to 50	23
51 to 60	18
61 to 70	11
71 to 80	2

In the writer's series of 127 cases of carcinoma of the bladder the incidence was as follows:

Age in Years	Cases
20 to 30	3
30 to 40	16
40 to 50	20
50 to 60	37
60 to 70	37
70 to 80	14

Of 144,774 cancer deaths in the United States during 1937, 4641 were due to cancer of the bladder. This 3.2 per cent incidence is about half that of cancer of the prostate and one fourth that of cancer of the breast. According to the Division of Vital Statistics of the Bureau of the Census figures then it is only one time in the United States there are from 15,000 to 20,000 cases of cancer of the bladder.

Sex.—In 153 cases of carcinoma of the bladder 119 were in males and 34 in females. This same ratio holds for papilloma.

Symptomatology.—The reason the diagnosis and treatment in a large majority of cases of tumor of the bladder are delayed from one to two years after the appearance of the first symptoms is that the physician himself does not consider seriously the one single symptom of hematuria.

Duration of Symptoms.—As will be seen from the following table the large majority of patients show the symptoms for over a year before the condition is diagnosed. In 101 cases (116 advanced and 5 early carcinoma) the following duration of symptoms was found:

Duration of Symptoms in Months	Cases
1 to 3	13
3 to 6	14
6 to 12	37
12 to 18	9
18 to 24	16
24	32

If the tumors in these cases had been diagnosed within three months of the appearance of the initial symptoms the percentage of cures could have been at least doubled.

First and Second Symptoms.—Hematuria and disturbances of urination are the two symptoms of greatest importance. While hematuria may be a symptom of many con-

ditions other than that of tumor of the bladder the fact that in 130 of 138 cases it was one of the symptoms shows the importance of recognizing this fact. Every patient presenting the symptom of hematuria should have a careful urologic examination. The symptoms of the disturbances of urination are not so important because anything that changes the contour, the capacity or the irritability of the bladder, the reservoir of the urine causes some changes in what is known as normal urination. One fact that should be kept in mind in making a differential diagnosis is the fact that tumors of the bladder rarely cause urinary retention while tumors of the prostate frequently do.

Renal Symptoms.—Because of ascending infection from the bladder (and many vesical tumors are infected) or because of some obstruction of the ureteral orifice about a third of all the patients with tumors of the bladder have considerable disturbance of the kidneys. This should always be kept in mind when the cure of a vesical tumor is undertaken because in most fatal cases the patient dies because of severe infection of the kidneys the function of which has been impaired.

Course.—Tumors of the papillary type may remain confined to the bladder for years. This is particularly true of pure papillomas and less so of papillary carcinomas. Spontaneous cure is unknown. Advanced tumors grow beyond the bladder generally to the retroperitoneal lymph nodes of the pelvis. They may invade the bones of the lumbar spine and pelvis and may invade the liver or the lungs. The osseous involvement is readily shown by roentgenograms and is generally of the osteoplastic type and therefore different from that of a prostatic carcinoma which is of the osteoclastic type.

Cystoscopic Examination.—Cystoscopy is carried out with two ideas in mind: first to obtain a general picture of the tumor and second to obtain a small specimen for pathologic examination. The specimens obtained by the cystoscopic forceps are very small indeed but as a rule quite sufficient for the diagnosis.

A rectal examination should never be omitted because an invasion of the base of the bladder may be distinctly felt in this way. Bimanual palpation should also be in

eluded as a tumor may thereby be felt extending suprapubically

Cystogram—The air cystogram has in late years assumed considerable importance in determining not the kind of tumor but the extent of the tumor. The procedure is quite simple. The catheter is introduced into the bladder, the fluid is withdrawn and air is pumped into the bladder gently and to the point of pain, then a roentgenogram is quickly taken.

Differential Diagnosis—The order of importance of conditions in the bladder which may be confused with carcinoma are (1) blood clot (2) simple ulcer (3) ulcer with encrusted encrustations (4) stone (5) tuberculous inflammation (6) leukoplakia (7) cystitis cystica (8) cysts of the prostate and (9) hypertrophied lobes of the prostate.

Treatment—In 177 out of 298 patients seen by the author at the Memorial Hospital the location of the tumor was near the urethra or near one or both ureters. The sizes of the base of the cancer in 298 cases were as follows: 40 were less than 5 sq cm, 56 were between 5 and 10 sq cm, 39 were between 10 and 20 sq cm and 86 were larger than 20 sq cm. In 7 cases the size was not estimated. This shows that 17 per cent of the cancers had bases between 10 and 20 sq cm and 39 per cent had bases of more than 20 sq cm.

These two conditions must be kept in mind when any treatment is considered. It must be realized that most vesical tumors are located in the base of the bladder and that most of them are extensive when first seen.

Treatment of Papilloma—If the diagnosis has been assured by the microscopic examination of a piece of the tumor, the tumor should be burned off with some form of electric spark, this treatment being called fulguration. This as a rule can be accomplished through the cystoscope. If the growth is too extensive, however, it will be necessary to make a suprapubic opening. It should be recognized that these tumors recur and that the patient must be watched cystoscopically for years. Extensive papillomatosis should be treated by total cystectomy and skin implantation of the ureters.

Popillary Carcinoma and Infiltrating Car-

cinoma—There are two schools at the present time each of which believes that its method of treatment is the proper one for tumor of the bladder. The first believes in the complete operative removal of the tumor with the removal of any part of the ureter that is involved and the disposal of the remaining portion of the ureter by different methods. Beer was the outstanding representative of this school. Since in most cases the tumor involves the base of the bladder the operation is difficult and fraught with considerable danger and the removal of part of the ureter may mean the destruction of the kidney which it drains, no matter what disposal is made of the ureter. The second school is represented by those who believe that radium presents the most adequate means of treating these tumors. This school of which the author is one believes that radium treatment of cancer of the bladder often can be accomplished successfully by means of the cystoscope with out any operation. If operation is undertaken and it is desirable to open up the bladder and implant radium in that way, the operative mortality of such an operation is considerably lower than if an attempt is made to cut out the tumor. Radium implantation as perfected is a comparatively simple procedure as compared with that of operative removal and the chance of destruction of one or the other kidney is considerably less. It is believed that in a large number of inoperable cases the condition can be controlled by radium therapy.

Summary of Five Year Results of Radium Treatment—Of 927 personal cases, unchecked and consecutive of bladder cancers seen up to and including the year 1937, 112 were papillary cancers and 143 infiltrating cancers. Of the 112 papillary tumors, 3 were operated on palliatively and 1 of the 143 infiltrating tumors, 10 were either not operated on at all or operated on for palliation. These 15 cases are excluded from the statistics because some of them had metastases on some the bladder was never felt through the suprapubic opening and in some a lesion was implanted because of hematuria. This leaves 109 papillary tumors and 133 infiltrating tumors. Of the 109 patients with papillary tumors the tumors of 20 were proved cured but the patients died of some intercurrent disease or were lost track of before the end of the five year period. The same was true of 12 of the 133 patients with infiltrating tumors. This leaves the following percentage of five year cures: Of 89 patients with papillary cancer there were 50 or 56.1 per cent, who were well for five years. Of 121 patients with infiltrating cancer there were

35, or 23.2 per cent, who were well for five years. Of 210 patients with combined papillary and infiltrating cancer, 85, or 40.1 per cent, were well for five years.

The pathologic diagnosis in all these cases has been made by examining pieces of the tumor obtained either cystoscopically or at the suprapubic exposure. It is never possible to obtain the entire tumor with its base for examination. Because of this the diagnosis has been modified by the clinical observations. If a tumor is reported as papillary cancer and if at operation the base of the tumor is found to be indurated that tumor is classed as infiltrating rather than papillary cancer. Such induration is gauged both by the actual feel and by the sense of resistance felt by the needle bearing radon seeds. These two methods are extremely accurate in determining induration and therefore classifying the tumor as infiltrating. In 17 cases there was no pathologic diagnosis or a diagnosis of papilloma. But 9 of these 17 are reported as five year cures. Thirteen patients died of cancer and 1 was lost track of. This indicates that the clinical diagnosis in these 17 cases was accurate. In our series "papillomas with atypical cells" were classed as papillary carcinomas. The malignancy in this class of cases has been doubted by some pathologists and urologists. There is no question that a small percentage of these tumors have been easily cured by various methods such as fulguration, excision and roentgen rays and do not act like malignant tumors. By far the larger percentage, however, have all the attributes of real malignancy. They react badly or not at all to fulguration and they tend stubbornly to recur. There is no pathologic or clinical means whereby one may distinguish between these two groups and until there is it is only fair and safe to group them under one class, papillary cancer.

Radium alone in different forms has been used to control these tumors. Suprapubic implantation was done 185 times and cystoscopic implantation 89 times in the 274 cases. These figures indicate that in 85 cases a combination of suprapubic and cystoscopic implantation was done to control the tumor.

If the tumor in question was reasonably small and situated in a part of the bladder which could be reached adequately through the cystoscopic treatment through the cystoscope was relied upon. This was done whether the tumor was papillary or infiltrating. We have lately successfully extended the scope of this method to larger tumors. It is the method of choice and if it can be accomplished saves time in the hospital, diminishes the hazards of operation and minimizes bladder and kidney infection. It takes persistent, repeated and intelligent cystoscopic treatment. When the suprapubic method is used the operation is simply a means to the end of implanting radon seeds into the tumor under direct vision. It is significant that in a fair percentage of cases both cystoscopic and suprapubic methods have been necessary to control the disease.²

Multiplicity of Tumors.—The Carcinoma Registry has emphasized that vesical cancer is more often multiple than single. The registry has even seen fit to change the pathologic diagnosis from papilloma to carcinoma on the clinical basis that carcinoma is multiple. From the clinical standpoint the fact that there are several tumors instead of one indicates in a broader

sense that multiple tumors constitute a malignant element as compared to a solitary tumor. On the other hand, from our records carcinoma of the bladder is usually single. In the cases in which control was obtained the carcinoma was single in 73 and multiple in 23 cases, in the cases in which control was not obtained, the carcinoma was single in 85 and multiple in 31.

Factors Influencing the Type of Therapy.—1 **Size of tumor.** Small tumors papillary or infiltrating, are best treated cystoscopically, with implantation of radon seeds or radon applications. Large tumors if papillary, are treated by means of suprapubic radon implants. Large tumors if infiltrating are treated according to the methods to be outlined presently.

2 **Grade of tumor.** Malignant growths of lower grades are treated as just outlined. Growths of higher grades particularly grade 4 are treated by external irradiation and cystoscopically.

3 **Position of the tumor.** When the tumor is on the base of the bladder (75 per cent of all tumors of the bladder) and encroaches on the ureters or the internal urethra irradiation is superior to operative removal. If cystotomy is necessary because of the size or site of the tumor, urethral catheters should be passed up the dilated ureters brought out of the suprapubic wound and left in place several days to insure proper drainage of the kidneys. If this is impossible there is a period of watchful waiting after the radon implantation. If one kidney becomes infected and causes sepsis which cannot be controlled then nephrectomy is the operation of choice, provided the remaining kidney is normal.

4 **Condition of the kidneys.** If the kidneys are infected and the ureters and renal pelves are dilated, cystoscopic treatment with radium is superior to open operation. The suprapubic operation and the massive implantation of radon seeds only extend the infection. The implantation or application of radium cystoscopically can be carried out in divided treatments.

Tumors of the bladder vault and extensive papillomatous should be operated upon the former by partial resection removing all fatty tissue overlying the bladder vault and the latter by cystectomy with skin implantation of the ureters.

Comparison Between the Results of Surgical and of Radiation Treatment.—Probably the best surgical results after five years show control in 25 per cent of cases. These results are computed on the basis of the total number of cases in which the tumor could be removed surgically. Obviously there are a large number of cases in which surgical intervention is impossible and the statistics do not include these. Our statistics include all cases in which the cancer was believed to be confined to the bladder. The size of the growth has not prevented an attempt to obtain a cure. The results of irradiation obviously must be better than the results of surgical treatment since we can report cures in 40.1 per cent of the cases in which treatment was given.

Disadvantage of Radium Treatment.—Implantation of seeds into an infected tumor increases the severity of the infection. A slough is always formed and presents a focus of increased infection. This slough may become encrusted with calcareous deposits and stone

formation may result Asepsis and a certain amount of antiseptics help obviate this condition Cleansing the bladder with antiseptic washes before and after cystoscopic implantation extreme care in the suprapubic approach and painting the tumor with a mild solution of iodine before the radium is implanted all help

Vesicovaginal fistula may occur either as a result of radon implantation or of the depth of the tumor or both There were 3 such cases in our series One patient died and 1 lived for five years dying of an acute renal infection One patient has lived for about two years and is reasonably comfortable after skin implantation of the dilated ureter of the single kidney

Suprapubic versus Cystoscopic Radiation—Not only the size of the tumor but the infection of the tumor and the condition of the kidneys should determine the method of treatment My colleagues and I are steadily leaning more and more toward cystoscopic treatment If the tumor is ulcerated and infected and if one or both kidneys are hydronephrotic suprapubic implantation of a large amount of radon is a dangerous procedure from the standpoint of the infection

Forms of Radiation Treatment—1 *Bulon Seeds* These have constituted the best method for both suprapubic and cystoscopic applications of radium

2 *X ray Alu* Much has been written of late about control by means of x ray treatment alone of cancer of the bladder Notwithstanding repeated and persistent attempts to control the more difficult types of vesical cancer deep x ray therapy in our hands has signally failed The reports of cases in which this treatment has been given have been singularly inadequate as to pathologic data and time of cure and there was failure in at least one such report to mention the essential fact that radium was used as an adjunct to the x ray treatment The use of x ray in the milder forms of cancer or papilloma of the bladder which could easily be controlled by cystoscopic fulguration or application of radium seems unjustifiable I have seen extremely severe effects after prolonged x ray treatment and I have known of 2 patients who died of skin destruction after such irradiation In 1 of these cases an infiltrating tumor had been controlled and the bladder was free from tumor In the other case there was marked regression of the tumor Most cancers of the bladder are radioinsensitive The present knowledge of how to give deep x ray therapy alone is sufficient to make cure possible in but very few cases This type of treatment may well be used as an adjunct to operation or radium treatment in cases of higher grades of malignancy particularly grade 4

3 *X ray Plus Rulon Seeds* I have attempted in 3 cases of extensive infiltrating ulcerated carcinoma to combine the first two types of treatment mentioned Radium is applied either cystoscopically or suprapubically Death has occurred in all 3 cases

4 *Fulguration and Surgical Diathermy* The only statistics recording five year cures of carcinoma of the bladder by surgical diathermy are those published by Counsellor and Brunsch from the Mayo Clinic They reported the end results in 17 cases of inoperable and non-resectable cancer They have an outstanding 88 per cent of five year cures This has never been duplicated by any other clinic

Many so-called loose reports have been made about

the removal of tumors of the bladder by means of the instrument used for transurethral resection of the prostate but no end results have as yet been reported The author cannot condemn too strongly the inadequacy of this last method

5 *Fulguration and X ray Therapy* Considerable work has been earned on lately with the instrument used for transurethral prostatectomy Extensive tumors of the bladder have been treated with fulguration followed by x ray therapy No extensive series as far as I know has been reported on It does not seem as though fulguration would work as an adjunct to x ray as does radium

6 *Preoperative or Postoperative X ray Treatment* Theoretically it seems that either of these procedures might so partially devitalize tumor cells that the operative removal would result in a larger number of cures I believe however that this is more a theoretical than a practical consideration At any rate I have not seen any reports of series of cases to substantiate the claim

7 *Application of Radium* The application of a large amount of radium gram 1 (unscreened) in a tumor for an hour at a time by means of the cystoscope and so under direct observation seems to offer a chance for the control of large ulcerating cancer of the bladder These growths are virtually beyond one's grasp at present This type of treatment is supplemented with deep x ray therapy I have seen several patients in whom this method has been effective With this type of therapy the infection in the tumor is not made worse, as is the case when radon seeds are implanted The suprapubic operation is omitted Only further work can determine however whether it will be possible to extend the number of cases in which control of cancer of the bladder is achieved by this method

Total Cystectomy and the Treatment of Tumors of the Bladder—Beer, Quinby, Smith, Hinman, Lower and others have believed that total cystectomy should be done in "a group of cases in which the trigone is so extensively involved that the ureters cannot be spared and both ureters have to be sacrificed In addition many of these cases have extensive involvement of the neck so that the infiltrating growth involves half or more of the splenic area and has invaded underlying tissues particularly the adjacent prostate tissues in the male In this group of extensive infiltrating growths situated at or in the neck of the bladder involving frequently the ureter orifices the problem is most serious What should we do? What can we offer these patients?"

With the improvement of surgical technique the mortality of this operation has been in the past fifteen years markedly reduced until at present it is between 15 and 20 per cent The mortality is considerably higher if the ureters are implanted in the intestines than if they are implanted in the skin I believe the latter method is certainly the operation of choice We must always remember however that the operation is severe and that even if successful there is no absolute assurance that the cancer has been eradicated I believe it should be used only as a last resort when appropriate methods of irradiation have been tried and have failed

thra Force or haste in massaging the prostate may result in failure to obtain any secretion

A sterile watch crystal or slide is held with the free hand under the meatus to catch all drops of the expressed secretion for microscopic examination in liquid state under $16\times$ power lens

The secretion from a normal prostate may contain from 1 to 5 white blood cells per field an infected prostate may show from 10 to innumerable white blood cells per field Some urologists feel that the presence of clumps of pus cells indicates a severe or a more chronic infection Secretion from a chronically infected prostate will appear free from bacteria by simple staining in 30 per cent or more of cases but cultures will be positive in 70 per cent of these cases according to Young Despite all attempts to obtain a clean secretion contamination of the prostatic fluid occurs in a large number of cases *Staphylococcus albus* and colon bacillus are by far the most frequent organisms found *Streptococcus* is found in 5 per cent *Bacillus pyocyaneus* in 1 per cent and the gonococcus rarely

It is impracticable in most cases to separate the prostatic secretion from the vesicular secretion This may be attempted however by massaging the vesicles and securing the contents in separate containers If no secretion is secured by massaging the prostate and seminal vesicles the patient is asked to void again frequently it is found that the expressed secretion has been forced backward into the bladder

Symptomatology and Diagnosis—Urethral discharge burning or tingling on urination lumbar pains loss of erections and sexual neurasthenia are common symptoms of prostatitis and seminal vesiculitis The symptoms are often vague and variable and one must undertake a careful examination in order to rule out other pathologic processes which cause similar symptoms Prostatitis must be differentiated from posterior urethritis verumontanitis papilloma of the vesical neck and the rare conditions such as tuberculosis cystitis and leukoplakia

The prostate is more frequently infected than the vesicles probably in the ratio of 10 to 1 The complication of epididymitis points very strongly to the vesicle as the site

of infection Hematospermia and nocturnal emissions of blood stained semen are symptoms either of chronic seminal vesiculitis or of inflammation of the verumontanum or both The latter can be ruled out by careful inspection with the cystourethroscope The ejaculatory ducts may be stenosed or completely closed by inflammation or scar tissue Sometimes they can be successfully probed through the urethroscope and made to function

The vesicles are rarely involved in chronic inflammation without involvement of the prostate except in tuberculosis This simplifies the burden of diagnosis because the treatment is much the same except in certain persistent types of vesiculitis in which surgical procedures are necessary for relief In many cases a prostate that feels normal as to size texture and consistency and that may be free from tenderness on pressure is chronically inflamed and contains many pus cells An infected vesicle is sensitive or painful to palpation Certain areas of increased hardness in the prostatic lobes or in the region of the most lateral portions of the prostatic capsule will lead the examiner to suspect carcinoma The age of the patient should be considered since chronic prostatitis is most frequently found in middle life and malignant growths are more frequent beyond the age of fifty years

We have now learned that cancer of the prostate may be undiagnosed for several years Keves has pointed out the fact that pain along the sciatic nerve on one side is suggestive of cancer of the prostate and when bilateral is pathognomonic Particularly is there apt to be found a hard almost boardlike area in the region of one or both vesicles in chronic perivesiculitis The vesicles are not so commonly the seat of cancer as is the prostate

Early cancer and chronic prostatitis with interstitial changes are difficult to differentiate Any area of hardness irregularity or nodule formation in the prostate of a patient past middle life should be considered as probably cancer until its character is determined by biopsy As carcinoma of the prostate advances one meets some difficulty in introducing a cystoscope through the prostatic urethra encountering hardened tissues and irregularities The trigone of the

bladder may be elevated. A roentgenogram of the pelvic bones, spine and lungs may show metastases.

If a definite amount of pus can be demonstrated in the expressed secretion in a doubtful case, gentle treatment for chronic prostatitis may be instituted for a few weeks before a biopsy is taken. In the writer's experience a number of such cases have yielded to mild therapeutic measures, proving them to be chronic inflammatory infiltrations and not new growths. If any suspicious nodules appear in the cystoscopic picture at the vesical neck, they can be easily and safely removed by the resectoscope for examination without the hazard of metastasis.

A chronically inflamed prostate may develop an increase of interstitial tissue compressing the prostatic urethra and resulting in slowness of the urinary stream and painful and frequent urination. These symptoms are much the same as those caused by prostatic hypertrophy with partial obstruction.

Treatment—Before treatment is begun a careful examination of the upper urinary tract is often advisable. Meatotomy should be performed if the urethral meatus will not admit a no. 27 French sound. Gradual dilation of the prostatic urethra is necessary to relieve the irritation in the prostatic urethra, to open the prostatic ducts and to help empty their contents. This also improves the circulation and aids the absorptive process in the gland itself.

The treatment which has been most successful in chronic prostatitis consists of gentle massage followed by lavage of the urethra and bladder with a mild antiseptic such as 1 to 1000 silver nitrate or 1 to 2000 copper sulfate. The lavage of the urethra and bladder serves to wash out the prostatic and vesicular detritus which is a potential source of urethritis and cystitis. Massage should not be carried out too frequently; a three to five day interval is best in ordinary prostatic infections, with a longer interval as the infection subsides. If pain is experienced or if blood tinged secretion is obtained longer intervals and less vigorous massage are indicated. In certain instances there may be cavity formation and prostatic calculi present and these should be removed. However, the chronically infected prostate is

rarely a surgical problem. Heat applied by hot sitz baths, irrigators or electrical apparatus directed to the prostate through the rectum and diathermy has been of great benefit.

It has been the fond hope of every urologist that chemotherapy would be found effective in sterilizing the chronically infected prostate, but little improvement has been noted from the use of sulfonamides or penicillin. The dyes represented by pyridium, mallophone and seranium are excreted to some degree in the prostatic contents and these drugs may have some beneficial influence in reducing the infection in the prostate and vesicles. On the whole, however, systematic treatment with drugs has been consistently disappointing.

After treatments have been carried out over a long period, a few patients will remain uncured and the prostate and vesicles may be a menace to the general health. Some suppurating pockets in the prostate may require open surgical drainage and in certain cases of arthritis in which the vesicles are thickened and contain pus, vesiculotomy or vesiculectomy may be necessary by the method of Fuller or the method so clearly described and expertly performed by Hugh Young. This will be necessary in only a very few cases but if they are properly selected brilliant results may be expected.

CARUS F. BURROUGHS

OTHER AFFECTIONS OF THE PROSTATE

PROSTATIC ABSCESS

Henceforth abscess of the prostate has generally been considered as a complication of gonorrhea. However, it is well to bear in mind that a great many of these cases are metastatic in origin and that abscess of the prostate has followed the passage of sound, bougies and cystoscopes and the use of strong injections. Again abscess of the prostate has been noted as a complication of such general infectious diseases as typhoid fever, mumps and influenza. Among other causes of suppuration that the writer has seen are furuncle, carbuncle, acute and chronic osteomyelitis and paronychia as well as acute tonsillitis. Abscess of the pros-

tate may be associated with benign hypertrophy but this is very rare Abscess has followed cases of urethral stricture due to poor and insufficient urethral drainage Abscess also frequently occurs as a complication of acute urethral gonorrhea and the gonococcus is found in the pus In the non venereal cases staphylococcus is the most frequent organism It may occur alone or associated with streptococci and colon bacilli

Symptoms and Diagnosis—There is no difference in the symptoms whether the abscess is of gonorrheal or non gonorrheal origin except that in gonorrheal cases a urethral discharge is present which shows gonococci Loss of appetite and a feeling of malaise soon follow The temperature may rise to 104° or 105° F and is often associated with one or more chills Pain is a constant symptom and may be due to the abscess itself or to distention of the bladder in cases in which complete retention of urine occurs Perineal pain may occur and is often accompanied by a feeling of fullness Frequency of urination is present in practically all the cases and may vary from a slight increase in frequency to a state in which the desire to void is so urgent that the patient is obliged to empty the bladder every fifteen to thirty minutes Retention of urine is quite common Complete retention in a young man should always arouse suspicion that the condition may be due to abscess of the prostate Retention occurs with equal frequency both in venereal and non venereal cases Abscess may cause obstruction at the neck of the bladder so that difficulty of urination occurs necessitating straining in order to start the stream Rectal symptoms such as pain on defecation with a feeling of warmth and fullness may be present

Rectal examination shows definite changes in the prostate Examination usually is very painful The prostate is increased in size and feels hot and tense and in some of the cases fluctuation can be elicited When the abscess is small there may be some question about the diagnosis but in ordinary cases the rectal examination is quite convincing Leukocytosis is present In some of the cases a mild eosinophilia occurs

The three possible terminations of an abscess of the prostate are resolution rupture or surgical drainage Cases that have gone on

to resolution are extremely rare though this is possible and does occur in some instances By far the largest number terminate by rupture into the urethra or into the rectum and occasionally into the bladder Rupture along side the rectum may develop into a perirectal abscess

Treatment—Hot sitz baths hot rectal irrigations and heat applied in the form of wet dressings to the suprapubic region and perineum give the patient a great deal of relief In some instances it is necessary to use morphine or codeine by mouth a rectal suppository containing belladonna or opium is often decidedly beneficial When these measures fail to give the desired relief and when the presence of fluctuation can be demonstrated on rectal examination operation is in order The abscess should be drained by means of a perineal prostaticotomy At the time of operation careful examination should be made so as not to overlook a second abscess or abscesses in the opposite lobe In some of these cases because of the presence of pus in the prostate after the wound is healed it is necessary to institute prostatic massage and advise the patient to continue heat per rectum The sulfid drugs are without value in the treatment

CYSTS OF THE PROSTATE

Cysts of the prostate are rare They may occur in the newborn and in children as well as in adults Some authors are of the opinion that they are due to closure of the Wolffian tubules In the newborn these cysts project into the urethra and produce obstructions to urination so that micturition is deferred for several days after birth

Etiology—According to von Frisch midline cysts originate from Muller's ducts while cysts placed laterally take their origin from remnants of the Wolffian body Retention cysts may be due to narrowing or closure of the prostatic ducts or may result from the fibrous tissue following inflammation in the prostate or urethra The walls of these cysts are smooth and thin and the cysts themselves are found to be more or less transparent when examined with the cystoscope

Symptoms—All cysts of the prostate produce the same symptoms When large they may cause obstruction to the outflow of urine In the adult they are occasionally confused with benign hypertrophy because of the symptoms of obstruction which they produce

Treatment—The treatment consists in destruction of the cyst by means of fulguration through the cystoscope

Echinococcus Cyst—Echinococcus lense rarely affects the prostate When this condition is encountered in the perineal region it is generally found between the bladder and the rectum The cyst may reach an

enormous size and interfere with urination and in rare instances it may cause complete retention. The ectomucococcus or mylenet fixation test is of great aid in diagnosis. The treatment is surgical.

Other tumors of the prostate except sarcoma, carcinoma and benign hypertrophy are rare.

PROSTATIC CALCULI

Prostatic calculi may be classified as being either true or false. True prostatic calculi are situated within the substance of the prostate. False prostatic calculi are urinary calculi that have become lodged in the prostatic urethra and really do not belong to the group of true prostatic stones.

Etiology—True prostatic calculi have their origin within the prostate itself. They consist in the main of phosphates, carbonates or deposits of lime, magnesium or triple phosphates. The etiology has not been definitely determined. Three theories have been advanced to explain their origin. (1) It is believed by many authors that the stones are due to a mild chronic infection of the excretory ducts of the gland. (2) Others are of the opinion that these calculi are formed by deposits of salts around a nucleus composed of normal prostatic secretions while (3) still others believe that prostatic calculi are formed by accumulations of corpora amylacea.

Prostatic stones are rare in patients under twenty years of age. Gonorrhea and syphilis have no etiologic bearing.

Symptoms—For the purpose of discussion the symptoms may be divided into three groups.

1 Cases in which calculi are found in a more or less accidental manner during a routine physical examination and in which the calculi do not produce any symptoms.

2 In this group may be placed the cases in which calculi are associated with benign hypertrophy of the prostate. The clinical picture is that of benign prostatic hypertrophy. The stones may be located within the gland structure proper or may be found between the hypertrophied gland and its capsule.

3 A group of cases in which the symptoms are due to the presence of calculi and the patient seeks relief because of the distress incident to the disorder. It is this group that is usually meant when the subject of prostatic calculi is discussed.

In nearly all the patients pain is present at some time or other during the course of the disease although in rare instances it may be absent. It may be localized to the prostate or referred to the perineum, urethra, penis, scrotum, anus or suprapubic area. rarely does pain extend to the posterior surface of the thigh. When pain is present in the perineum it is greatly aggravated by sitting on a hard surface. In the occasional case a history of the passage of prostatic calculi *per urethram* is given. Abscess formation with or without fistula is rare. The urinary symptoms naturally predominate. The patient complains of painful urination, burning, dribbling and difficulty in starting the stream. Sexual symptoms are rare but loss of potency has been recorded in some cases.

Rectal symptoms such as tenesmus, pain in the rectum and painful defecation are not unusual symptoms. In the occasional case stricture of the urethra may occur.

Diagnosis—Stones in the prostate can be definitely established in every case by means of roentgenograms and stones in the prostate may be found in cases in which the usual symptoms are absent. As a rule multiple shadows are present. They may be located on one or the other side of the midline just above the symphysis pubis or they may occur on both sides of the midline. Their grouping is not always constant.

Next to roentgenograms in value from the standpoint of diagnosis is the rectal examination. When the stones are large they can be felt with the examining finger and a sense of crepitation is obtained. This however is not always evident. Areas of great hardness should always arouse suspicion of the possible presence of calculi and a roentgenogram should be taken for the reason that calculi are frequently overlooked during a rectal examination.

Treatment—The treatment varies somewhat in each case. Small multiple calculi that are not producing symptoms but are discovered during a routine examination do not call for radical treatment. Stones associated with benign hypertrophy can be treated at the time when prostatectomy is performed.

In the third group of cases that is the group in which the patients have symptoms, radical removal of the calculi can best be performed by perineal prostatectomy. It is

tite may be associated with benign hypertrophy but this is very rare Abscess has followed cases of urethral stricture due to poor and insufficient urethral drainage Abscess also frequently occurs as a complication of acute urethral gonorrhea and the gonococcus is found in the pus In the non venereal cases staphylococcus is the most frequent organism It may occur alone or associated with streptococci and colon bacilli

Symptoms and Diagnosis—There is no difference in the symptoms whether the abscess is of gonorrheal or non gonorrheal origin except that in gonorrheal cases a urethral discharge is present which shows gonococci Loss of appetite and a feeling of malaise soon follow The temperature may rise to 104° or 105° F and is often associated with one or more chills Pain is a constant symptom and may be due to the abscess itself or to distention of the bladder in cases in which complete retention of urine occurs Perineal pain may occur and is often accompanied by a feeling of fullness Frequency of urination is present in practically all the cases and may vary from a slight increase in frequency to a state in which the desire to void is so urgent that the patient is obliged to empty the bladder every fifteen to thirty minutes Retention of urine is quite common Complete retention in a young man should always arouse suspicion that the condition may be due to abscess of the prostate Retention occurs with equal frequency both in venereal and non venereal cases Abscess may cause obstruction at the neck of the bladder so that difficulty of urination occurs necessitating straining in order to start the stream Rectal symptoms such as pain on defecation with a feeling of warmth and fullness may be present

Rectal examination shows definite changes in the prostate Examination usually is very painful The prostate is increased in size and feels hot and tense and in some of the cases fluctuation can be elicited When the abscess is small there may be some question about the diagnosis but in ordinary cases the rectal examination is quite convincing Leukocytosis is present In some of the cases a mild eosinophilia occurs

CYSTS OF THE PROSTATE

Cysts of the prostate are rare They may occur in the newborn and in children as well as in adults Some authors are of the opinion that they are due to closure of the sinus plicularis In the newborn these cysts project into the urethra and produce obstructions to urination so that micturition is deferred for several days after birth

Etiology—According to von Frasel midline cysts originate from Mullerian ducts while cysts placed laterally take their origin from remnants of the Wolffian body Retention cysts may be due to narrowing or closure of the prostatic ducts or may result from the fibrous tissue following inflammation in the prostate or urethra The walls of these cysts are smooth and thin and the cysts themselves are found to be more or less transparent When examined with the cystoscope

Symptoms—When small cysts of the prostate produce few symptoms When large they may cause obstruction to the outflow of urine In the adult they are occasionally confused with benign hypertrophy because of the symptoms of obstruction which they produce

Treatment—The treatment consists in destruction of the cyst by means of fulguration through the cystoscope

Echinococcus Cyst—Echinococcus disease rarely affects the prostate When it is encountered in the perineal region it is generally found between the bladder and the rectum The cyst may reach an

enormous size and interfere with urination and in rare instances it may cause complete retention. The echinococcus complement fixation test is of great aid in diagnosis. The treatment is surgical.

Other tumors of the prostate except sarcoma, carcinoma and benign hypertrophy are rare.

PROSTATIC CALCULI

Prostatic calculi may be classified as being either true or false. True prostatic calculi are situated within the substance of the prostate. False prostatic calculi are urinary calculi that have become lodged in the prostatic urethra and really do not belong to the group of true prostatic stones.

Etiology—True prostatic calculi have their origin within the prostate itself. They consist in the main of phosphates, carbonates or deposits of lime, magnesium or triple phosphates. The etiology has not been definitely determined. Three theories have been advanced to explain their origin: (1) It is believed by many authors that the stones are due to a mild chronic infection of the excretory ducts of the gland; (2) others are of the opinion that these calculi are formed by deposits of salts around a nucleus composed of normal prostatic secretion; while (3) still others believe that prostatic calculi are formed by accumulations of corpora amylacea.

Prostatic stones are rare in patients under twenty years of age. Gonorrhea and syphilis have no etiologic bearing.

Symptoms—For the purpose of discussion the symptoms may be divided into three groups:

1. Cases in which calculi are found in a more or less accidental manner during a routine physical examination and in which the calculi do not produce any symptoms.

2. In this group may be placed the cases in which calculi are associated with benign hypertrophy of the prostate. The clinical picture is that of benign prostatic hypertrophy. The stones may be located within the gland structure proper or may be found between the hypertrophied gland and its capsule.

3. A group of cases in which the symptoms are due to the presence of calculi and the patient seeks relief because of the distress incident to the disorder. It is this group that is usually meant when the subject of prostatic calculi is discussed.

In nearly all the patients pain is present at some time or other during the course of the disease although in rare instances it may be absent. It may be localized to the prostate or referred to the perineum, urethra, penis, scrotum, anus or suprapubic area. rarely does pain extend to the posterior surface of the thigh. adhesions that may be present so as to prevent the formation of more stones.

BENIGN HYPERTROPHY

Definition—Benign hypertrophy is a disease of the prostate that is rare before the age of fifty and occurs with greatest frequency after fifty-five. It is characterized by

urinary tract and it is accompanied by difficulty in urination. It has a progressive course and is fatal unless relieved by appropriate treatment.

Etiology—Advanced age is the one factor that is always present the majority of the

* Lewis: Practice of Surgery. W. F. Prior Co. Publishers.

patients being between fifty five and seventy years of age. After seventy the incidence of this disease decreases. The oldest patient the writer has seen with prostatic obstruction was ninety nine years and ten months old. Gonorrhea and syphilis play no role in the development of this disease. Formerly it was thought that gout, rheumatism and alcohol played a predominant role but this is not true. Heredity is unimportant, although there seems to be a tendency for this condition to occur in families. On one occasion the writer had as patients in the hospital at the same time three brothers who were suffering from benign hypertrophy.

Various theories have been advanced from time to time to explain the cause of hypertrophy. 1 The arteriosclerotic theory was promulgated by the French school of urologists who considered the hypertrophy to be due to or a manifestation of arteriosclerosis that involved

origin of hypertrophy. 6 Deming from his investigations is of the opinion that the early changes of benign enlargement of the prostate in man are primarily due to a multiplication of the fibromuscular elements.

Pathology.—The enlargement of the gland varies within very wide limits. Attention may be called to the fact that the size of the prostate has nothing to do with the severity of the symptoms nor the degree of obstruction. An unusually large prostate may produce only mild disturbance while, on the other hand, a very small adenoma at the internal urethral orifice may produce exceedingly severe symptoms.

Much discussion still centers around the question of whether benign hypertrophy is a true neoplasm or a hyperplastic process. The majority of urologists believe that it is due to hyperplasia and is not a true tumor formation.

Fig 665—*a* Trilobar hypertrophy of the prostate *b* showing the groove made by the internal sphincter with intravesicular protrusion of the middle lobe.

not only the prostate gland but the bladder and kidneys as well. 2 The inflammatory theory has but few advocates at the present time. The English surgeon Thompson was one of the earliest authors to believe that inflammatory changes in the prostate played no role in the etiology. Several years ago the interest in the inflammatory origin of hypertrophy was revived by the work of Ciechanowski who believed that hypertrophy and also certain form of prostatic atrophy are due to chronic inflammatory changes in the prostate. This theory has practically no adherents today. 3 The neoplastic theory was upheld by Virchow who was of the opinion that so-called hypertrophy is caused by a true tumor formation. However, the question of whether or not true hypertrophy is a new growth or is due to hyperplasia is still a much disputed point. 4 Disturbed physiology is considered by some authors to be the cause of hypertrophy. This opinion is based on the fact that hypertrophy occurs at a time of life when the function of the testicle is on the wane, the hypertrophy being considered as a compensatory function for the diminished or diminishing sexual function. 5 At the present time a good deal of thought and investigation is being directed to the possible endocrine

Types of Enlargement.—Tandler and Zuckerkindl have divided hypertrophy into two groups—*intravesicular* and *subvesicular*.

Intravesicular Type.—The internal urethral orifice is changed both in shape and in position. The size of the enlargement varies from that of a small plum to that of a lemon or it may be larger. It may be more or less pedunculated or it may completely surround the internal urethral orifice hence its outline may be either regular or irregular. The enlargements are most marked on the sacral side of the internal urethral orifice. Cases in which the enlargement entirely surrounds the urethral orifice have been compared to the cervix uteri. The internal urethral orifice is always elevated above its normal location. A groove caused by the compression of the internal sphincter may be seen in the specimen removed by suprapubic prostatectomy.

Subvesicular Type.—Under this type Tandler and Zuckerkindl group all cases in which the protrusion is below the internal sphincter. There is no intravesicular protrusion but the internal urethral orifice is enlarged.

Point of Origin.—At the present time the general consensus of opinion is to the effect that the hypertrophy takes its origin from the accessory glands.

from the tubules and not from the prostatic gland proper. Among the authors who are of this opinion may be mentioned Rokitsansky, Jores, Tanler and Zuckerkandl, Blum and Rubrins. Lowsley states that these glandular tubules are present in the anlagen in the embryo after the sixteenth week. Others share this view. Motz and Percarnau are of the opinion that the origin of prostatic hypertrophy is from the central group of tubules and that the prostate itself does not take part in the formation of the tumor.

Gross Description.—The size of the enlarged prostate may vary within wide limits. Prostates have been removed that weighed as much as 500 Gm. The writer has removed a small prostate that weighed 90 grams which produced complete obstruction. The enlargement, as a rule, is uniform although one lobe may be larger than the other. The surface is smooth and surrounded by a smooth capsule and the consistency is elastic. The cut surface is light in color and connective tissue septa are seen running in from the periphery. Prostatic fluid exudes from the cut surface. When the prostate is infected, small milary abscesses may be seen on the cut surface.

Microscopic examination shows the presence of an epithelial hyperplasia with the formation of villi in some cases. The presence of cystic dilatation of the acini is noted in a large number of instances. The epithelial lining of the acini may be flattened and as the dilatation increases they become more and more compressed so that only the nuclei can be seen. The lumen of the tubules may be filled with finely granular material that contains leukocytes and starch granules. Desquamated epithelial cells are also evident. The changes in the stroma vary from a slight overgrowth in the connective tissue to a great increase in the fibrous tissue, periglandular round cell infiltration often being seen.

Changes Due to Obstruction.—The elongation of the prostatic urethra occurs very early and was recognized many years ago and was utilized as an aid in diagnosis. Instead of the normal curve of the prostatic urethra it forms in some cases a right angle with the lateral lobes which protrude irregularly into it so that it has an S shaped curve. At times the wall of the bladder may be very greatly thickened; this occurs at the expense of the bladder capacity so that a small contracted bladder results (concentric hypertrophy). The muscle bundles also undergo hypertrophy and show elevations above the surface which are delicate in character and few in number at first. As the disease progresses the elevations increase in size and number and become very thick and coarse. Sooner or later cellular formation occurs.

Diverticula often very large are not uncommon. Dilatation of the ureter and renal pelvis occurs in various degrees. If the ob-

struction is allowed to persist complete atrophy of the kidneys may result.

Relationship of Benign Hypertrophy to Carcinoma of the Prostate.—Opinion is divided on this point. Some authorities believe that carcinoma may take its origin in the enlarged lateral lobes. Geraghty, on the other hand, was firm in the belief that carcinoma always begins in the posterior lobe that is in the portion of the prostate not involved in the hypertrophy.

Median Bar.—The interest in median bar formation began with the publication of a monograph by Guthrie in 1830. In this group of cases the symptoms are practically the same as those produced by large hypertrophies. Rectal examination reveals a prostate that is normal in size although not infrequently it has been found to be smaller than normal. The term prostatism has been in use for many years to describe this type of case. The classification given by Randall as a result of much careful work is as follows:

TYPE I.—A fibrous bar in type arising from or stretched across the posterior lip of the vesical orifice. This type produces shortening of the distance from the vesical orifice to the verumontanum.

TYPE II.—A fibrous bar, the projection of which is upward or toward the bladder and seems to encroach on the vesical trigone.

TYPE III.—A glandular bar in which the hypertrophied process is confined to the glandular remnant of the posterior prostatic commissure inside the prostatic capsule under the sphincter muscle so that the posterior vesical lip is raised into a thick broad heavy obstructing bar.

TYPE IV.—Isolated hypertrophy of the subcervical glands of Albarran.

Symptoms.—The symptoms in this group of cases are practically identical with those produced by hypertrophy. The patients have frequency and difficulty of urination and attacks of acute retention of urine. Residual urine in varying amounts is present.

Rectal examination reveals a small prostate often smaller than normal and cystoscopic examination fails to show the presence of an intravesical hypertrophy.

The gradual onset and slow progress are characteristic manifestations of this disease.

One symptom that is always present is

frequency of urination that is mild in the early stages and slow in progress. Nocturnal frequency of urination is characteristic of prostatic obstruction. Early in the course of the disease the patient may void only once or twice at night but later it is often necessary to void every half hour or hour.

Difficulty of urination is not very marked early in the course of the disease but is progressive and the patient often finds it difficult to start the stream. In some instances the patient can pass only a few drops of urine with the greatest effort. The difficulty may be overcome by changes in posture. In some instances the patient is obliged to wait one or two or even three minutes before he can start the stream. Lack of force is often accompanied by loss of power of propulsion so that the patient is compelled to stand close by during urination.

Dribbling at the end of the act is complained of by many patients as an inconvenience which may also be due to incontinence resulting from overflow, so called paradoxical incontinence.

Hematuria.—Gross bleeding is not a common symptom. Blood at the end of urination often associated with straining, has been noted. When profuse bleeding occurs the bladder may become filled with clots. The bleeding may be aggravated or increased by the passage of instruments.

Polyuria.—In some instances the patient may have an associated polyuria and may pass large quantities of urine as much as 4 or 5 liters during twenty-four hours.

Pain.—Pain referred to the urethra and associated with the act of urination is present in from 75 to 80 per cent of cases. It varies in degree from a mild burning sensation along the urethra to severe pain. The pain may be referred to the neck of the bladder, the perineum, the end of the urethra or the back, thighs or rectum.

Complete Retention of Urine.—Complete retention of urine in the prostatic patient may be induced by constipation, exposure to cold, chilling of the body and getting the feet wet. Overindulgence in alcohol and long automobile trips often induce an attack of complete retention. Acute infectious processes such as influenza, coryza and tonsillitis have been followed by acute complete retention.

Sexual Symptoms.—As a rule the sexual symptoms are not very prominent. Because of the age of the patient there is more or less diminution of sexual vigor. In some instances the decided improvement in the patient's general health following removal of the prostatic obstruction results in a return of a degree of sexual vigor. Repeated attacks of acute epididymitis occur in some patients before they are seen by the physician.

Gastrointestinal Symptoms.—Gastrointestinal symptoms are not always present but when they are it is generally late in the course of the disease. Loss of appetite occurs in the later stages, particularly in cases in which there is an associated severe infection of the urinary tract. Excessive thirst with associated polyuria is seen at times. Constipation is a frequent symptom and in some cases is due to the enormously enlarged prostate which mechanically interferes with the act of defecation. Hemorrhoids are often present in cases characterized by severe tenesmus and great obstruction. In some cases prolapse of the rectum has been noted. Inginal hernia is not an uncommon symptom and is no doubt due to the excessive straining which is incident to the obstruction.

Cardiovascular Symptoms.—A large number of patients suffer from various cardiovascular symptoms such as angina pectoris, hypertension, arteriosclerosis, myocarditis and coronary disease. In a recent survey of 100 patients 63.3 per cent had associated organic disease of the cardiovascular system.

Complications.—The most frequent complication of prostatic obstruction is infection which may be limited to the bladder or may involve the kidney and ureters as well.

Naturally because of the presence of residual urine cystitis is the most common complication of prostatic obstruction. Local conditions which are favorable for infection are residual urine, chronic distention of the bladder and hypertrophy of the mucous membrane so that the passage of a sound catheter or cystoscope is often followed by acute cystitis.

In patients who have not had instrumentation urethritis is rarely present. On the other hand a patient who is under treatment with an indwelling catheter may acquire so called catheter urethritis. This is

due to the presence of a catheter which acts as a foreign body to the fact that the catheter prevents the escape of normal urethral secretion and furthermore to the fact there is no flushing of the urethra by the urine. *Epididymitis* is a relatively frequent complication of prostatic obstruction. It has been variously estimated that epididymitis occurs in from 20 to 25 per cent of all patients including the occurrence of epididymitis before as well as after operation.

Diverticula—Diverticula of the bladder with benign obstruction are not uncommon. It is important to recognize the presence of a diverticulum before treatment is undertaken. In certain cases failure to remove the diverticulum is responsible for the persistence of pyuria following removal of the obstruction.

Stone—Stone in the bladder is a relatively common complication. Prostatic stones are uncommon; nevertheless stones may be found associated with obstruction without the presence of infection. Stone formation following prostatectomy is not a frequent occurrence although the persistence or recurrence of symptoms following removal of the obstruction should always arouse suspicion as to the possible presence of stones.

Renal Complications—Acute pyelitis may occur following the passage of a catheter. It may occur immediately before or directly after operation and it is characterized by a sudden onset of severe chill, high fever and pain in the renal area. Chronic pyelitis occurs in patients with dilatation of both renal pelvis and ureters. The infection is probably not limited to the pelvis but involves the renal parenchyma producing chronic pyelonephritis.

Hydronephrosis probably occurs more frequently than is suspected as is evidenced by the fact that intravenous pyelograms frequently show the presence of hydronephrosis when it is not suspected. Suppurative pyelonephritis with the formation of small milky abscesses may develop. These abscesses may be hematogenous in origin or they may be the result of extension of infection along the lumen of the ureter from the bladder. Abscess of the prostate associated with hypertrophy is relatively rare. Stones may be found in the prostate but they are generally small and are located beneath the capsule.

Diagnosis—The symptoms of prostatic obstruction are typical and a definite diagnosis may be made from the history and physical examination although in a few cases the general symptoms may overshadow the disturbances of urination.

Rectal Examination—Rectal examination yields valuable information regarding the size, shape and consistency of the prostate. It is probably the most satisfactory method of examination by which to establish a correct diagnosis. Generally the two lateral lobes are equally enlarged although not necessarily so in every case. In some cases the enlargement is only moderate; in others the enlargement may fill the bony pelvis. The surface is generally smooth and the margins are sharply defined. In cases associated with much infection there is evidence of prostaticitis. The consistency which is characteristic of benign hypertrophy is softness and elasticity. Despite the fact that rectal examination gives an amount of information that is invaluable it fails to yield information regarding the amount of enlargement which may be present within the bladder or within the urethra.

Estimation of Residual Urine—This is a relatively simple procedure and when properly performed it yields a great deal of information regarding the patient's ability to empty the bladder. Estimation for residual urine (the amount obtained by catheterization after the patient has voided) should be carried out under strictest antiseptic precautions. Next to the rectal examination it is the most important diagnostic procedure.

Changes in the Urethra—Formerly a great deal of stress was laid on the measurement of the posterior urethra as an aid in the diagnosis of benign hypertrophy. While this is of anatomical interest it is of little use as an aid in establishing the diagnosis.

Cystography—Cystograms may be made with a sterile solution of potassium bromide or iodide. The strength used varies from 5 to 15 per cent. The cystogram shows the size of the bladder and the changes in its outline. It occasionally reveals the presence of diverticula where least expected and in some instances the reflux of the solution up the ureter shows the presence of a large hydronephrotic ureter and hydronephrosis.

Intravenous Pyelography—While not necessary in every case intravenous pyelography often shows the presence of unsuspected diverticula or hydronephrosis.

Cystoscopic Examination—Examination of the vesical orifice with the cystoscope and with the rectoscope yields information regarding the intravesical and intraurethral type of hypertrophy. These methods of examination demonstrate very clearly whether there is enlargement of the lateral lobes, bars or median lobes, etc., and may reveal the presence of stone, benign or malignant tumors and diverticula. These procedures must be carried out with a certain amount of care and under the strictest antisepsis and asepsis possible. It is best not to examine a patient who has a severe infection or a large amount of residual urine without some preliminary treatment.

Differential Diagnosis—1 *Carcinoma*—In the largest number of patients differentiation between benign hypertrophy and carcinoma is relatively simple and easy, although in some cases a small area of carcinoma located in a large lateral lobe may be overlooked on rectal examination. A carcinomatous prostate always shows changes in consistency, varying from areas of the slightest increased consistency to a degree of hardness that has been described as stony. Irregularities in outline are often present, and the tendency for carcinoma to extend beyond the confines of the prostate is well known. The seminal vesicles are often involved early and the intervesicular space is infiltrated by the carcinoma.

2 *Chronic Prostatitis*—Patients with chronic prostatitis often have only slight enlargement of the prostate. Strippings give a large amount of pus. The absence of residual urine and careful cystoscopic examination are important and constitute indispensable aids in the making of a differential diagnosis.

3 *Calculi* may be associated with benign hypertrophy. Rectal examination often elicits areas that are very hard in consistency and a sense of crepitation may be present. Roentgenographic examination is an invaluable aid.

4 *Abscess of the prostate* is rare. Rectal examination reveals fluctuation in one or both lobes. The patient often has acute

symptoms sudden in onset accompanied by chills, fever and sweats.

5 *Sarcoma of the prostate* is rare and gives a peculiar sensation to the finger on rectal examination when present.

6 *Echinococcus disease* of the prostate can be differentiated by the echinococcus complement fixation test.

7 *Lesions of the Central Nervous System*—It is well known that lesions of the central nervous system produce urinary symptoms that may be confused with prostatic hypertrophy. It must not be forgotten that lesions of the central nervous system can be associated with benign hypertrophy. In ordinary differentiation, rectal examination shows the absence of hypertrophy of the lateral lobes and loss of tone in the rectal sphincter, the knee jerks are absent and there is an Argill Robertson pupil. If any doubt exists a Wassermann test of the blood or spinal fluid should be made. Cystoscopic examination is of great aid.

8 *Strictures of the urethra* may be associated with or confused with benign hypertrophy, although as a rule stricture of the urethra is uncommon in persons at prostate age. The presence of stricture can be demonstrated by exploration of the urethra with diagnostic bougies.

9 *Lesions of the kidney* are rarely confused with benign hypertrophy. In rare instances malignant tumor of the kidney may be associated with benign hypertrophy.

Prognosis—Benign hypertrophy is a progressive disease and unless the obstruction is removed leads to death of the patient. This fatality is not due to the disease *per se* but to the complications following in the wake of the obstruction, such as infection and uremia. With removal of the prostate the prognosis is good.

Treatment—1 *Prophylactic Treatment*—At the present time there is no treatment that will prevent enlargement of the prostate.

2 *Non Operative and Hygienic Treatment*—Chilling of the body should be avoided and the feet should be kept dry and warm. The skin should be protected with warm underwear in cold weather. Long cold automobile trips, as well as sitting on damp ground or cold stones, should be avoided. The patient should be encouraged

tatectomy is performed. Bleeding may be controlled by suture or by the use of a rubber bag or a gauze pack. Hemorrhage occasionally occurs two weeks after operation and then is always due to infection.

Complications of surgical prostatectomy are shock, pyelitis, fistula, dilatation of the stomach, bronchitis, pneumonia, pulmonary embolism and phlebitis. Cardiac complications occur less frequently than formerly because of a more careful preoperative study of the patient with heart disease. Cerebral thrombosis is rare. Coronary occlusion at the neck of the aorta and myocardial failure are uncommon.

Urogenital complications developing after operation are acute epididymitis which occurs in 20 per cent of the cases, stricture of the urethra which is more frequent after perineal than after suprapubic prostatectomy, and occasionally fistula after either suprapubic or perineal prostatectomy. Incontinence of urine is rare. Impotence occurs in a small number of cases and when it does it is generally permanent. Stone in the bladder must be considered as a rare complication occurring in about 2 per cent of cases. Recurrence following complete removal of the prostate is rare but it does occur. It is characterized by the fact that a long interval exists between the removal of the prostate and the development of the symptoms of recurrence.

The mortality has been variously estimated at from 4 to 9 per cent.

Transurethral Resection.—At the present time transurethral resection is the method most frequently used to relieve prostatic obstruction. Its advantages are an exceedingly low mortality rate, the short period of postoperative hospitalization and the applicability of this technique to patients who heretofore have been denied relief of symptoms because they were poor surgical risks. The mortality varies from 1 to 2 per cent. I have performed 238 consecutive resections with 1 death. Perfect hemostasis is most important here as in any surgical procedure. It is needless to emphasize that complete removal of the obstruction is imperative. I never fol-

low to 3 per cent of the cases here longer perform bilateral vasectomy. Instruments and methods have been improved: the cold punch of Young, the punch of Caulk, the so-called Bumpus punch, the Stearns-McCart sectoscope and many others.

CARCINOMA

Etiology.—The etiology of carcinoma of the prostate is unknown. Recently, however, an endocrine theory has been advanced. In general, the basis for this theory is as follows: It has been observed that carcinoma of the prostate is often extremely sensitive to the presence of androgens and that if the hormone can activate the growth of prostate cancer. In many patients the inactive hormone neutralization of this hormone brings about retrogression of the cancer cells. Previous sections such as gonorrhea play no part in its development. Cancer of the prostate is rare in persons under fifty and occurs with the greatest frequency between the ages of sixty and seventy. Bumpus in a study of 1000 cases found the average age to be sixty-five years. Almost 50 per cent of cases occurred in patients between the ages of sixty and seventy.

Pathology.—Roughly, two types of carcinoma are recognized. In one the prostate shows hardly any change from the normal and in the second the prostate is enlarged and nodular and often shows extension of the carcinoma beyond the confines of the gland. In the first form the prostate is normal in size or may be somewhat enlarged. It is of very hard consistency and the surface may appear to be practically normal. This type of prostate is often found in cases in which extensive bone metastases are present; hence were it not for the bone metastases the prostate might be overlooked as the seat of carcinoma. In the second, larger group the prostate is definitely enlarged and the surface is nodular and irregular. The consistency has been variously described, a favorite term being stony hardness. The disease spreads toward the ureters so that many times the ure-

tions of drugs into the testicle to produce fibrosis are methods that have historical interest only and are of no use today.

PRELIMINARY PREPARATION.—It is extremely important that each prostatic patient have a complete physical examination before operation or before special examinations are undertaken. As previously mentioned cardiovascular lesions are present in 63 per cent of the patients and it goes without saying that these patients are benefited by close cooperation between the internist, the cardiologist and the urologist. Preliminary study and preoperative preparation of the patient have contributed more to the reduction of the mortality rate than any other single factor. Impaired cardiac function demands rest in bed and some form of digitalis and the fluid intake must be limited. Hypertension is deserving of careful consideration. It is not uncommon to see the

urine and a rapid decompression of the bladder is very apt to have fatal results.

The determination of renal function by means of a blood chemical examination and phenolsulfonephthalein test should be carried out in every case. Renal function will show marked and rapid improvement as treatment progresses.

CONTROL OF INFECTION.—Infection is best controlled by drainage and by the administration of large quantities of fluid, also by *irrigation of the bladder.* Drainage may be obtained by means of an indwelling catheter or a preliminary suprapubic cystostomy. Undoubtedly in the largest number of patients infection can be controlled with the indwelling catheter although this method has certain limitations in that some patients complain of pain while in others it produces urethral discharge, bleeding, chills and fever. When these complications develop it is better to perform a cystostomy under local anesthesia.

CHOICE OF ANESTHESIA.—Inhalation anesthesia is being used less frequently and ether should never be used. Ethylene is the inhalation anesthetic of choice. Sternal anesthesia either alone or combined with paracervical anesthesia enjoys a popularity at the present time and when carefully given in the hands of an experienced anesthetist is successful in over 90 per cent of cases. Some surgeons prefer spinal anesthesia. At the present time sodium pentothal is very widely used.

CHOICE OF OPERATION.—The prostate may be removed in one of three ways: (1) by suprapubic or perineal prostatectomy or (2) by transurethral resection.

Suprapubic prostatectomy may be performed in one or two stages and the prostatectomy itself may be performed by division of the internal urethral orifice and enucleation of the prostate with the finger.

Perineal prostatectomy following the technique of Young is the most popular method of prostatectomy at the present time.

Control of hemorrhage at the time of operation is of the greatest importance because these patients stand loss of blood very poorly. When there is considerable hemorrhage at the time of operation a transfusion should be given. Some surgeons make it a rule to give a blood transfusion before pros-

to take a certain amount of light exercise such as golf or walking. There is no objection to moderate horseback riding. A diet consisting of fresh and cooked vegetables and fresh and stewed fruits is recommended. There is no objection to meat in moderation although the heavier red meats should be used sparingly. Overeating at banquets has often been followed by an attack of acute retention. Alcoholic drinks in moderation are not harmful which is best illustrated in some elderly patients who accustomed to a daily glass of wine with their meals are in a better condition with than without it. The bowels should be kept open by means of suitable diet or with a mild laxative such as cascara, compound licorice powder, castor oil or enemas.

The patient should be instructed to empty the bladder regularly and especially to void as soon as possible when the desire is present. Hot sitz baths at night give a great deal of local comfort and in some cases reduce the number of voidings during the night. Hot rectal irrigations or the use of the Artz burger tube will be found beneficial.

Massage of the prostate in the early stages may relieve the symptoms. Roentgen ray treatment has no particular value. The injection of drugs into the prostate is a waste of time.

TREATMENT OF ACUTE COMPLETE RETENTION—When acute retention of urine develops every attempt to establish spontaneous urination should be tried before catheterization is instituted. The fluid intake should be limited. The application of hot water bags to the perineum and above the pubes often results in spontaneous urination. If this fails hot sitz baths are in order. If there is pain during the attack morphine sulfate hypodermically or belladonna and opium in the form of a rectal suppository are indicated. If these measures fail the use of the catheter becomes imperative. Catheterization should be carried out only under the strictest aseptic precautions. A soft rubber catheter should be used first and if this cannot be passed without trauma a Coude catheter may be tried. At the present time rubber catheters with a right angle beak are obtainable and they can often be passed when the ordinary soft rubber catheter fails. A metal catheter should be used only as a

last resort. The urine should be withdrawn slowly, the amount withdrawn depending on the amount in the bladder. It is better to remove it in small quantities even in cases of acute retention.

In cases in which it has been impossible to pass a catheter, suprapubic puncture has been carried out. In the hands of a specially qualified surgeon this is a simple procedure and gives a good deal of relief. A catheter may be introduced into the cannula after the trocar is withdrawn and left in place for the purpose of drainage. However it is important to call attention to the fact that this procedure is not necessarily free from danger, injury to the intestines followed by fatal peritonitis being a possibility in cases in which there is a low insertion of the peritoneum. On account of the possibility of this danger this method is rarely used today.

TREATMENT OF CHRONIC INCOMPLETE RETENTION—Residual urine should be withdrawn daily followed by lavage of the bladder with potassium permanganate 1:4000 or silver nitrate 1:5000. A small quantity of the irrigating fluid may be allowed to remain in the bladder or boric acid solution may be used and argyrol 10 per cent or protargol 1 per cent or nargol 2 per cent injected into the bladder after the irrigation.

TREATMENT OF CHRONIC COMPLETE RETENTION—Patients in this group all require operative treatment and unless the retention is relieved must lead a catheter life.

Palliative treatment in this type of case is carried out only during the period of preliminary study. When admitted to the hospital the patient has a suprapubic tumor. The appetite is poor and the tongue is dry. It is exceedingly important that withdrawal of the urine should not be completely done but gradual decompression practiced. Rapid or complete withdrawal of the urine has been followed by severe hemorrhage or by acute ascending infection of the kidney with uremia and death. It is advisable in these cases after the catheter has been passed to fix it in the urethra so as to institute catheter drainage.

3. Operative Treatment—Ligation of the iliac artery, castration, division of the cord or resection of the vas deferens and injec-

tions of drugs into the testicle to produce fibrosis are methods that have historical interest only and are of no use today.

PRELIMINARY PREPARATION.—It is extremely important that each prostatic patient have a complete physical examination before operation or before special examinations are undertaken. As previously mentioned cardiovascular lesions are present in 63 per cent of the patients and it goes without saying that these patients are benefited by close cooperation between the internist, the cardiologist and the urologist. Preliminary study and preoperative preparation of the patient have contributed more to the reduction of the mortality rate than any other single factor. Impaired cardiac function demands rest in bed and some form of digitalis and the fluid intake must be limited. Hypertension is deserving of careful consideration. It is not uncommon to see the blood pressure fall when infection and fibrin have been corrected. The diabetic patient can withstand operation provided the proper preoperative preparation is instituted. Other complications such as chronic bronchitis, asthma and emphysema should be carefully studied before operation and the condition improved as much as possible. Infections of the mouth should be thoroughly eradicated before surgical treatment is undertaken. Some surgeons believe in the preoperative administration of some sulfa drug to prevent postoperative reactions such as fever.

IMPAIRED RENAL FUNCTION.—One of the important methods of examination of this group of patients is the estimation of the renal function. When it is not normal it can be greatly improved with treatment. It is important to remember that renal function must be stabilized before operation is undertaken. The importance of fluids in the treatment of impaired renal function cannot be overemphasized. Fluids should be administered by mouth, per rectum and if necessary by saline infusion. In some cases it may be necessary to administer as much as 5000 or 6000 cc. of fluid in twenty-four hours. During the administration of large amounts of fluid care must be exercised not to overload and embarrass the heart. It is necessary to decompress the bladder gradually because many of these patients have high residual

urine and a rapid decompression of the bladder is very apt to have fatal results.

The determination of renal function by means of a blood chemical examination and phenol sulfonephthalein test should be carried out in every case. Renal function will show marked and rapid improvement as treatment progresses.

CONTROL OF INFECTION.—Infection is best controlled by drainage and by the administration of large quantities of fluid also by lavage of the bladder. Drainage may be obtained by means of an indwelling catheter or a preliminary suprapubic cystostomy. Undoubtedly in the largest number of patients infection can be controlled with the indwelling catheter although this method has certain limitations in that some patients complain of pain while in others it produces urethral discharge, bleeding, chills and fever. When these complications develop it is better to perform a cystostomy under local anesthesia.

CHOICE OF ANESTHESIA.—Inhalation anesthesia is being used less frequently and ether should never be used. Ethylene is the inhalation anesthetic of choice. Spinal anesthesia either alone or combined with paracervical anesthesia enjoys a popularity at the present time and when carefully given in the hands of an experienced anesthetist is successful in over 90 per cent of cases. Some surgeons prefer spinal anesthesia. At the present time sodium pentothal is very widely used.

CHOICE OF OPERATION.—The prostate may be removed in one of three ways, i. e., by suprapubic or perineal prostatectomy or by transurethral resection.

Suprapubic prostatectomy may be performed in one or two stages and the prostatectomy itself may be performed by division of the internal urethral orifice and enucleation of the prostate with the finger.

Perineal prostatectomy following the technique of Young is the most popular method of prostatectomy at the present time.

Control of hemorrhage at the time of operation is of the greatest importance because these patients stand loss of blood very poorly. When there is considerable hemorrhage at the time of operation a transfusion should be given. Some surgeons make it a rule to give a blood transfusion before pro-

tatectomy is performed. Bleeding may be controlled by suture or by the use of a rubber bag or a gauze pack. Hemorrhage occasionally occurs two weeks after operation and then is always due to infection.

Complications of surgical prostatectomy are shock, pyelitis, fistula, dilatation of the stomach, bronchitis, pneumonia, pulmonary embolism and phlebitis. Cardiac complications occur less frequently than formerly because of a more careful preoperative study of the patient with heart disease. Cerebral thrombosis is rare. Coronary occlusion, attacks of angina and myocardial failure are uncommon.

Urogenital complications developing after operation are acute epididymitis which occurs in 20 per cent of the cases, stricture of the urethra which is more frequent after perineal than after suprapubic prostatectomy and occasionally fistula after either suprapubic or perineal prostatectomy. Incontinence of urine is rare. Impotence occurs in a small number of cases and when it does it is generally permanent. Stone in the bladder must be considered as a rare complication occurring in about 2 per cent of cases. Recurrence following complete removal of the prostate is rare but it does occur. It is characterized by the fact that a long interval exists between the removal of the prostate and the development of the symptoms of recurrence.

The mortality has been variously estimated at from 4 to 9 per cent.

Transurethral Resection.—At the present time transurethral resection is the method most frequently used to relieve prostatic obstruction. Its advantages are an exceedingly low mortality rate, the short period of postoperative hospitalization and the applicability of this technique to patients who heretofore have been denied relief of symptoms because they were poor surgical risks. The mortality varies from 1 to 2 per cent. I have performed 238 consecutive resections with 1 death. Perfect hemostasis is most important here as in any surgical procedure. It is needless to emphasize that complete removal of the obstruction is imperative. Fever following resection occurs frequently but is of short duration. If it is high or lasts more than a few days one of the sulfa drugs should be given. Epididymitis occurs in only

2 to 3 per cent of the cases hence I no longer perform bilateral vasectomy. Various instruments and methods have been developed: the cold punch of Young, the hot punch of Caulk, the so-called Birsch, Bumpus punch, the Stearn-McCarthy resectoscope and many others.

CARCINOMA

Etiology.—The etiology of carcinoma of the prostate is unknown. Recently, however, an endocrine theory has been advanced. In general the basis for this theory is as follows. It has been observed that cancer of the prostate is often extremely sensitive to the presence of androgens and that this hormone can activate the growth of prostatic cancer. In many patients the inactivation or neutralization of this hormone brings about retrogression of the cancer cells. Previous infections such as gonorrhea play no role in its development. Cancer of the prostate is rare in persons under fifty and occurs with the greatest frequency between the ages of sixty and seventy. Bumpus in a study of 1000 cases found the average age to be sixty-five years. Almost 50 per cent of his cases occurred in patients between the ages of sixty and seventy.

Pathology.—Roughly two types of carcinoma are recognized. In one the prostate shows hardly any change from the normal and in the second the prostate is enlarged, hard and nodular and often shows extension of the carcinoma beyond the confines of the gland. In the first form the prostate is normal in size or may be somewhat enlarged. It is of very hard consistency and the cut surface may appear to be practically normal. This type of prostate is often found in cases in which extensive bone metastases are present hence were it not for the bone metastases the prostate might be overlooked as the seat of carcinoma. In the second and larger group the prostate is definitely enlarged and the surface is nodular and irregular. The consistency has been variously described a favorite term being stony hardness. The disease spreads toward the seminal vesicles so that many times the prostate and seminal vesicles form one hard nodular mass. The carcinoma may spread toward the bony pelvis. Because of the spread to the seminal vesicles and the invasion of the

pelvis, the prostate has often been described as "frozen in the pelvis." Involvement of the urethra and bladder occurs. Carcinoma may extend around the neck of the bladder in the form of villous growths and in rare instances nodules are seen under the mucous membrane of the trigone. It may spread and involve the rectum and obstruct the bowel movement. Perforation of the rectum is rare but the writer has seen this several times. Carcinoma may extend to the lower end of the ureter producing obstruction with resulting hydronephrosis. Attention may be called to the fact that not all cancers of the prostate show the change in consistency previously described hence when this is absent it can readily be understood why the condition is sometimes overlooked.

Microscopically cancer of the prostate is adenocarcinomatous. In some cases the glandular elements predominate and the tumor is soft. When the fibrous tissue elements predominate the term scirrhous carcinoma is used.

Point of Origin.—Carcinoma may begin in the posterior lobe or more correctly in the posterior lamellae or it may take its origin in one or both lobes of a normal prostate. It may also begin in hypertrophied lateral lobes. Carcinoma and hypertrophy may occur at the same time. In some instances because of the presence of benign hypertrophy the carcinoma is overlooked at the time of operation and the diagnosis is not made until sections have been examined microscopically. Young states that 50 per cent of the cases of carcinoma of the prostate seen in his clinic were associated with hypertrophy of both the lateral and the median lobes.

Metastases.—Carcinoma of the prostate like carcinoma of the breast and thyroid tends to produce bone metastases. In some instances symptoms of bone metastases overshadow the urinary symptoms. The bony structures most frequently involved are those of the pelvis and spine (pelvis 20 per cent spine 20 per cent). Metastasis may occur in any bony structure. The ribs and femur probably next to the pelvis and spine are most frequently involved. The predominating lesion is the production of new bone so-called osteosclerosis although osteoporosis may be present with

osteosclerosis. Sometimes the osteoporosis predominates and this accounts for the spontaneous or so-called pathologic fractures. Metastases to the retroperitoneal glands probably occur much earlier than is generally believed because of the difficulty in demonstrating them by palpation and physical examination on account of their deep position. The inguinal and femoral glands as well as the cervical and axillary glands may be the seat of metastatic disease.

Symptoms.—In the largest number of cases the urinary symptoms predominate in the clinical picture and are characterized by obstruction at the vesical orifice. Urinary symptoms may be of recent origin. Rectal examination reveals the presence of an extensive cancer. In some cases the symptoms of obstruction occur late in the course of the disease. Frequency of urination both day and night associated with difficulty and pain are the symptoms most frequently present. This group of symptoms may be due to the cancer itself or to the associated hypertrophy of the lateral and middle lobes. Complete retention of urine occurs late in the disease although the writer has known this to be the first symptom to bring the patient to the hospital for examination. Gross hematuria may occur but it is rare. Pain in the back over the sacrum or in the renal area and along the course of the sciatic nerve is often present. This may be due to bone metastases or to the pressure of the retroperitoneal extension of the cancer on the nerves. Bilateral sciatica in a man with urinary symptoms should always arouse suspicion of the possibility of carcinoma of the prostate. Spontaneous fracture may be the first symptom presented by the patient. Rectal symptoms such as pain in the rectum constipation and painful or difficult defecation occur late. Proliferation of the carcinoma into the rectum as previously mentioned occurs but is relatively uncommon.

Diagnosis.—Rectal examination is of the greatest importance in establishing a diagnosis. A careful rectal examination should reveal any changes in the consistency as well as in the contour of the prostate. Increase in the firmness of the gland as well as slight irregularity of the surface should at

can arouse suspicion that the disease is a carcinoma. The presence of small hard nodules is of great value in arriving at a diagnosis. In a well developed case there is no difficulty in making a diagnosis on the basis of a rectal examination. An enlarged hard nodular prostate with extension to and involvement of the seminal vesicles presents no problem in diagnosis.

In the average case cystoscopic examination is of but little value in arriving at the correct diagnosis. It is of value in demonstrating the presence or absence of other lesions of the bladder such as stone, diverticula and so forth. It is also of value in demonstrating the presence of carcinomatous involvement of the neck of the bladder.

Ferguson advises aspiration of the prostate through the perineum as an aid in diagnosis of early carcinoma. Roentgen examination for the presence of bone involvement is of great value especially in cases in which rectal examination is of little value. At times it is difficult to differentiate these bone changes from Paget's disease. Finally in some cases carcinoma is not recognized until after the histologic examination of the removed prostate.

Differential Diagnosis.—Difficulties may be experienced in relatively young men in whom the consistency of the prostate has changed and by reason of this there is confusion with chronic prostatitis. Stone in the prostate can be demonstrated by the roentgen ray (see section on Diagnosis of Stone in the Prostate). Tuberculosis is rare at the time of life when carcinoma occurs and generally the patient presents other evidences of tuberculosis in the genital or urinary tract.

Prognosis.—In some cases the growth is very slow. The duration of life after the diagnosis has been made has been estimated at about three and a half years. This depends somewhat on whether the patient presents himself early in the course of the disease or whether metastases are present at the time examination is made.

Treatment.—Treatment may be considered under four headings: (1) perineal prostatectomy, (2) treatment with radium or roentgen rays, (3) treatment directed toward relief of obstruction and (4) endocrine therapy.

1 *Perineal prostatectomy* with or without the removal of the seminal vesicles has been recommended by Young. In a series of 599 operations for cancer of the prostate life was prolonged in 246 patients for more than five years.

2 *Roentgen Ray and Radium Treatment.*—Radium may be applied in one of two ways: by radium emanations inserted into the prostate after perineal exposure or by the introduction of the radium element into the prostate through the perineum with radium needles. The latter method is more simple. Applications of radium through the urethra or through the rectum are rarely used today. There can be no question that radium treatment often causes marked reduction in the size of the carcinoma and no doubt inhibits its growth. Some surgeons prefer the use of deep roentgen rays to radium.

3 *Relief of obstruction* may be obtained by suprapubic cystostomy or transurethral resection. Both procedures have the same objective: namely, to relieve complete retention and to relieve the obstruction at the vesical neck, thereby preventing secondary changes to the ureters and kidneys. Suprapubic cystostomy is rarely employed at the present time. Transurethral removal of the obstruction (electroresection, cautery punch) relieves the obstruction and avoids the necessity of permanent suprapubic catheter drainage. When the obstruction recurs a second resection can be performed. Following the removal of the obstruction by transurethral resection treatment with radium or deep roentgen rays should be employed as an adjunct.

4 *Endocrine Therapy.*—This can be accomplished in two ways: by castration and by the administration of estrogens. There is at present some difference of opinion as to whether these two forms of therapy accomplish the same clinical result. It should be emphasized that both of these methods of therapy do not cure prostate cancer. The time is still too short to evaluate the end result from these forms of therapy.

SARCOMA

Sarcoma of the prostate is a rare disease. The literature contains reports of only 192 cases.

Etiology—As in sarcoma in other parts of the body the etiology is unknown. In approximately one third of the reported cases sarcoma occurred before the age of ten years but it may occur at any time of life. Adams reported a case in a patient aged eighty-eight.

Pathology—Practically every type of sarcoma has been reported. Round and spindle cell rhabdomyosarcoma and leiomyosarcoma occur in about 50 per cent of cases. Among other types may be mentioned angiofibromyxofibrolymphomyxochondrosarcomas. The most frequent sites of metastases are the kidneys, inguinal glands, lungs, liver, pleura and the retroperitoneal glands.

Symptoms—In a large number of cases the tumor has reached an extensive growth before the patient consults a physician. Because of the pressure on the bladder, urethra or rectum disturbances of micturition and defecation are often present. Hematuria may occur. Pain along the course of the sciatic nerve may occur in rare instances. Complete retention of urine, edema of the lower extremities and of the scrotum, loss of weight and anemia are later manifestations.

Course—As a rule the disease runs a very rapid course. The average duration of life after the onset of symptoms is about one year.

Diagnosis—In general the diagnosis is relatively easy to make. Rectal examination shows the presence of a large soft and smooth mass in the prostatic area. In the adult the presence of an enlarged prostate of a peculiarly elastic consistency is highly suggestive. The condition can generally be differentiated from carcinoma which is more nodular and irregular in outline. Tuberculous abscess and stone offer no special diagnostic problems. Great care should be exercised to differentiate between primary sarcoma of the prostate and primary retroperitoneal sarcoma that has extended to the prostate.

Treatment—The most favorable results have been obtained with radium and deep ionizing ray therapy. Surgical treatment is indicated only for the relief of obstruction.

THE MALE EXTERNAL GENITALS
INJURIES OF THE PENIS AND URETHRA

The location and mobility of the distal aspect of the penis and urethra afford these structures some immunity to direct injuries while the fixed portion which penetrates the triangular ligament and the part immediately in front of this ligament are especially susceptible to both direct and indirect injury because of their anatomical location and immobility. Any portion may receive injuries from sharp penetrating objects both from the outside and from within the urethra.

The flaccid penis may be dislocated from its coverings and displaced under the skin of the scrotum, pubis or thigh. This uncommon injury is thought to be due to a force applied to the extremity. The tear occurs at the sulcus back of the corona. Rupture or so called fracture of the penis occurs from bending or sudden direct force applied to the organ during erection causing a tear of the fibrous sheath of the corpora cavernosa. The injury is very painful and the penis becomes edematous which together with hematoma produce a distorted markedly enlarged structure bent away from the side of the ruptured sheath. Conservative management consisting of elevation of the part, ice packs and later sometimes incision to relieve hematoma is indicated.

Strangulation resulting from the application of a ring or other similar inelastic substances about the penis by insane persons or by others probably unstable mentally for purposes of masturbation is not uncommon in institutional work. There is interference with the blood supply, swelling occurs and the constricting object is often buried deep in the tissues. Gangrene and complete separation of the distal segment may occur if the constriction is not soon relieved. Constrictions of much less severity occur but these persons frequently do not present themselves for treatment until acute urinary retention has resulted which may be too late to save the distal segment intact. The treatment consists of removal of the constricting band.

The removal of the integument of the penis by accidents with machinery to which the clothing has been caught impinging the skin of the penis resulting in its removal in whole or in part is occasionally observed. Some cases of criminal mutilation are encountered in which the penis has been completely stripped of its integument. Plastic operations and skin grafts are usually necessary but the remarkable regenerative capacity of the integument of the penis and scrotum should always be kept in mind.

Straddle injuries of the bulb and bulbous urethra are common usually caused by the weight of the falling body when striking a fixed object the force of the fall being applied to the perineum in the region of the bulb. Variable degrees of injury result from contusion of the bulb and urethra to complete maceration of these structures. The extent of the injury usually determines the symptoms but the swelling resulting from a relatively minor injury to the tissues may produce urinary retention and complications.

Symptoms—The most common symptoms are perineal pain shock urethral bleeding and difficult or impossible urination. The intraurethral bleeding appears at the external urinary meatus and is not associated with the act of urination except to be aggravated by it as a result of the compressor action of the bulbocavernosus muscle.

Treatment—An injury not sufficient to produce intraurethral bleeding or interference with urination should be treated by local application of icebags and should be under careful observation. The hematoma may absorb but may require incision.

External urethrotomy is frequently necessary in order to stop the bleeding relieve urinary retention and remove the hematoma. Urethral dilations must be carried out for many months so as to prevent the development of a stricture.

INJURIES OF THE SCROTUM AND TESTICLE

The normal relative mobility of the scrotum and its contents allows these structures some protection against any ordinary type of injury. Gunshot wounds and injuries acquired by sharp objects in motion are

among the notable exceptions resulting in injury to the scrotum and its contents in varying degrees from laceration of the scrotum to marked destruction of the testicular tissue which may necessitate its removal.

Dislocation of the testicle from its scrotal site is caused by sudden blows it is seen in horseback riders and in persons who have had an accident in which a vehicle wheel passed over the body. The testicle is usually driven out under the skin overlying the pubis but may lodge under the skin of the penis or in the groin. Replacement by manipulation or surgical means should be effected immediately otherwise atrophy occurs. A more common condition is the temporary forcing of the testicle into the inguinal canal under the stress of a sudden blow which simulates a true dislocation symptomatically.

The most common injury to the scrotum and testicle results from a fall astride some fixed object and the forcing of these structures against the symphysis pubis. Obviously these injuries vary directly with the directness and extent of the force applied. *Hematocele* is a common result of injuries caused by crushing direct blows. A firm smooth tender mass is produced that does not transmit light. It usually absorbs but may need to be evacuated surgically. Because of clots aspiration is either difficult or impossible.

Torsion of the testicle is rotation of the testicle in either direction with from one to four half turns. The blood supply is interfered with as a result of the twist in the spermatic cord. The condition is more common than supposed as it is frequently mistaken for epididymitis. A normal testicle probably could not be so rotated which implies that some anatomical abnormality is present. The condition occurs in undescended testes in about half the cases. The following anomalies have been given as possible causes: the abnormal attachment of the common mesentery and vessels to the lower pole of the testicle and globus minor; the elongation of the globus minor; a capacious tunica vaginalis and the incomplete attachment of the epididymis to the scrotum. Sudden muscular effort is frequently the exciting cause but the condition has occurred during sleep. Thrombosis of the

vessels below the twist and varying degrees of necrosis of the testicle depending on the length of time since the onset are present. The symptoms include sudden severe pain in the testicle associated with shock, nausea and sometimes vomiting. Examination early reveals a painful swollen testicle the differentiation between the testicle and epididymis by palpation is soon lost and the scrotal tissue becomes edematous. Later the pain subsides but the testis remains tender and swollen. There is fever and leukocytosis. In an undescended testis the condition simulates strangulated hernia while in the descended testis excepting for its onset it suggests epididymitis.

Treatment—Early recognition and surgical relief are successful and imperative since later treatment either conservative or surgical cannot prevent atrophy. It has been suggested that the anomaly which makes the condition possible is bilateral hence the other testicle should be more closely fixed to the bottom of the scrotum as a prophylactic measure.

STRUCTURE OF THE URETHRA

Structure of the urethra is an organic narrowing of this structure which is usually caused by scar tissue.

Congenital stricture is due either to a developmental defect or to an early unrecognized infection which causes stenosis of the meatus at the peno-scrotal junction or at the bulbomembranous junction. It is usually recognized by frequency and difficulty of urination sometimes associated with dribbling. Patients with chronic emprostia should be examined for this defect. Meatal stricture is apparent on inspection but the deeper ones are diagnosed only by instrumentation. Meatal strictures must be cut while the deeper ones may respond to dilation.

Traumatic stricture is the result of scar tissue developed following injuries of the submucosal tissues. In the anterior urethra

it commonly results from improper instrumentation or a straddle injury of the bulbous portion while in the posterior urethra fracture of the bony pelvis with urethral injury is the chief cause. Traumatic stricture develops within a few weeks or months following injury, whereas inflammatory stricture requires a much longer time for its presence to become apparent.

Inflammatory strictures are almost all of gonococcal origin chaneroid and chanere about the meatus and tuberculous being exceptions. The severity of the gonococcal infection rather than its chronicity produces stricture. Careful gentle treatment of gonorrhea prevents this complication while judicious instrumentation and the use of strong antiseptics intensify the infection and tend to produce stricture.

Pathology—A stricture is essentially a fibrous scar in the urethral wall usually started in the lamina propria about the urethral glands and lacunae. Contracture of the scar makes further narrowing up to the point of almost complete occlusion at times. As the glands are on the floor and lateral walls the scar tissue predominates there the lumen being toward the roof. A stricture may be a single band or may cover an area of several square centimeters. Multiple strictures may be present the lumens of which are progressively narrower as the posterior urethra is approached. Liberation of the mucosa often occurs both in front and behind a strictured area which accounts for the presence of coarse leathery shreds in the first voided urine. Perurethral abscesses and urinary extravasation sometimes result. Prostatitis and seminal vesiculitis usually supervene and spontaneous repletion of the lumen is not unusual. The amount of residual infected urine is usually not great but hypertrophy or dilatation of the bladder results followed by dilatation and ascending infection of the upper urinary tract in longstanding severe cases.

The symptoms are those of chronic urethritis i.e. a gleet discharge and later frequency and difficulty of urination associated with dribbling and sometimes incontinence. Acute urinary retention may occur as a result of local congestion brought on by exposure to wet and cold voluntary retention of urine or instrumentation.

The diagnosis is not difficult to make after obstructive symptoms appear. Too often the necessary examination is not made when chronic discharge alone is present. The use of bulbous bougies and sounds to dilate the urethra establishes the diagnosis.

Prophylactic treatment consists of careful gentle treatment of the gonorrhea. Active treatment is preferably by dilation. In certain cases of tough stricture of the shaft of the penis internal urethrotomy is required while stricture of the bulb that does not admit a filiform bougie must be opened by external urethrotomy. Whether treatment is primarily by dilation or by cutting dilating instrumentation must be continued at increasing intervals for months or years until all tendency of recontraction has disappeared. Infections of the genital and upper urinary tract must be appropriately managed.

The course taken by the periurethral infection depends on the virulence of the bacteria as well as on the tissue resistance of the host. If the local periurethral tissues maintain control the infection remains localized and a periurethral abscess is formed; however if local conditions are not favorable for localization the infection spreads as cellulitis. The course of the cellulitis is determined by the fascial planes of the pelvis and penis (Fig 666).

Superficial infiltration results from erosion proximal to a stricture usually of the bulbous portion which allows infection to become periurethral into the superficial ti-

Fig 666.—Showing the fascial planes which determine the course of phlegmonous infiltration.

PHLEGMONOUS INFILTRATION

(Urinary Extravasation)

Phlegmonous infiltration formerly called urinary extravasation is a condition in which infection extends beyond the urinary channel at a point made vulnerable by ulceration. This point is usually just proximal to a structured area of the anterior portion of the urethra. It has been presumed but never proved that urine accompanies the infection. Since this complication often occurs in the presence of large caliber (18 to 20 F) strictures the directing force could not be adequate here to force urine into the periurethral tissues.

The course of the phlegmon is prevented from going back of the triangular ligament by its ventral attachment to Colles' fascia. The latter directs the effusion forward into the superficial tissues of the scrotum, penis and abdominal wall. Infiltration starting distal to the posterior attachments of Buck's fascia is confined to superficial tissues of the penis by this fascia. Both types of superficial infiltration require external urethrotomy and multiple incisions to effect drainage of the tissues involved.

Deep urinary extravasation results from breaks back of the triangular ligament. By far the most common cause is urethral injury associated with a fractured pelvis.

Urine is forced into the periprostatic tissues, it soon becomes perivesical and finally may extend up on the abdominal wall separating the peritoneum from the transversalis fascia. Usually the diagnosis is obvious when the patient is first seen, but with peritoneal irritation and its associated protective muscular rigidity, intra abdominal lesions may be suspected.

The management is always surgical and includes the providing of suprapubic drainage of the bladder and perivesical tissues, also realignment of the ruptured and tortuous urethra and the maintaining of the abgument with a firm indwelling urethral catheter.

TUMORS OF THE TESTICLE

Tumors of the testicles are not common. They occur once in every 2000 male admissions to the hospitals and represent 0.57 per cent of all malignant tumors in men being relatively more common in the undescended than in the normally placed organ.

Etiology.—The tumors occur in infants, boys and men, the greatest incidence being between the ages of twenty and fifty, the tumors very uncommonly appearing before puberty. Trauma as a factor, is open to various interpretations. About 50 per cent of the histories cite trauma of some sort, but the causal relationship still remains to be proved. The chronic irritation and direct trauma to which an incompletely descended testicle is subjected may be a factor. The frequency of epididymitis and the relative rarity of testicular tumors probably indicate no causal relationship, however, some tumors are first apparent following such an infection. Himm states that "it is doubtful whether single injuries to a normally placed organ do more than call attention or act as a stimulus to an already existing growth."

Pathology.—Benign tumors of the testicle are very rare. Fibroma of the tunica albuginea and true leiomyoma have been observed. As a rule, tumors of the testicle are malignant, being among the most malignant of all neoplasms.

The older literature abounds with names for different cell arrangements. This confusion was somewhat

cleared when, with better histologic methods and careful study of serial sections, it was discovered that the majority of these tumors have a teridermal constitution and are in fact teratomas. There is still lack of unanimity in their classification, some authors believing that practically all are teratomas, while others hold that there is a second group of pure tumors originating from the cells of the seminiferous tubules.

It is well to recognize two main groups: (1) mixed tumors (teratomas) and (2) pure cell types (seminomas).

Mixed tumors are derived from all three primary germinal layers. The derivatives from all three layers are frequently found but owing to overgrowth of one cell type, one germinal layer derivative may be missing or really overlooked in the section. The most common type of teratoma has a teridermal cell arrangement in no definite form and bears little or no resemblance to a full organ, while the more highly differentiated dermoids (rare) may contain teeth, hair, bones and other tissues recognized as being, from almost every organ of the body. Any one of the three types of cells become malignant and about half of all testicular tumors are teratogenic carcinomas. Chorionic carcinomas are a rare type of teratogenic tumor that behaves like as elsewhere. Pure cell types of tumor, the seminoma of Cleverly (known by Fung as *testicular lowers as monodermal teratomatous derivatives*) are derived from the epithelium of the seminiferous tubules and represent about 40 per cent of all testicular tumors.

Sarcoma, formerly considered the most common tumor of the testicle, undoubtedly is the rarest if as such it exists at all.

Melanoses from tumors of the testicle occur primarily by way of the lymphatics. The lymph vessels follow the course of the spermatic vessels and drain into four to six lumbar retroperitoneal lymph nodes alongside the vena cava and aorta, respectively. Secondary nodes are in the pelvis along the iliac vessels. The inguinal nodes are not involved unless the scrotum is involved or unless there is a back up from the primarily involved lumbar region. Blood vessel dissemination does occur in some cases, especially in chorionic carcinoma.

Symptoms.—There is no characteristic clinical picture. Usually there is first noticed a painless swelling of the testicle, without tenderness. There is sometimes a period of quiescence and then, owing to trauma or for no apparent reason, the growth becomes rapid. As a rule, the course is rapid and without early and adequate management the condition is fatal within a year. Symptoms and findings of lymphatic involvement before the testicular tumor is apparent are not infrequently observed, especially in teratomas. Symptomatic hydrocele is common.

The diagnosis is principally a matter of exclusion. The growth may be slow or very rapid and the tumor may be small or very large and complicated by hydrocele. The

shape of the testicle is usually maintained until later when nodulations may appear. Syphilis (tertiary), tuberculosis, non specific epididymitis, hydrocele and hematocele may afford problems in diagnosis.

Zondek has demonstrated that in most cases of testicular tumor a gonadotropic substance is liberated in the urine. This substance is now known to be present in diagnostic amounts in approximately 85 per cent of testicular tumors. Dean states that this test cannot be used to determine the histological type of tumor because there is no close correlation between the hormone level and the type. The test is of definite value in making a prognosis because in general those with a high level die sooner than those with a low level. It has since been proved that with other conditions a similar hormone may be liberated and that irradiation of a testicular tumor temporarily affects the liberation of this hormone. Nevertheless testing for this hormone is a valuable adjunct in diagnosis and after operation it may anticipate the prognosis.

Prerestoration due to incompleteness of positive diagnostic findings may waste valuable time when early surgical treatment might effect a cure.

Treatment—The superficial location of the normally placed and inguinal testes would seem to afford early recognition of such lesions. That only 15 per cent of cures are obtained by simple castration is ample proof of the fact that extension beyond the testicle has usually resulted before the diagnosis is made.

A radical operation consisting of removal of the testicle, the cord and the retroperitoneal lymph vessels and nodes *en masse* while it is a much more hazardous surgical procedure (10 per cent surgical mortality) than simple castration has resulted in cures in 30 per cent of suitable cases according to Himmans' statistics. When there is palpable evidence of glandular metastases the tumor is inoperable by either simple or radical methods. In these cases radium packs and roentgen therapy may prevent the progress and prolong life. The results obtained with preoperative irradiation have not been convincing. After either type of surgical treatment a thorough course of radium or roentgen therapy is indicated.

Coley's fluid while not generally conceded to be of value here has been reported as being of value as an adjunct in the diminution and retardation of the growth and amelioration of the symptoms.

Success in the management of these tumors obviously depends on early recognition and removal of the tumor bearing area followed by thorough irradiation. Obsecure chronic testicular enlargements should not receive palliative management over unnecessarily long periods of time. Surgical exploration is indicated.

SPERMATOCELE

Spermatoceles are retention cysts originating in the vasa efferentia, the tubules connecting the epididymis to the testicle. Whether these cysts arise from complete or from aberrant tubules with blind endings and are not connected with the epididymis is an unsettled academic question.

Of several causative factors considered the one most commonly held is that a cyst results from obstruction of one of the vasa efferentia with subsequent dilatation. Likewise dilatation of aberrant vasa efferentia with blind endings must also be included. They occur in persons twenty five to fifty years of age, small ones are often found in older men. They vary in size from nonclinical pea sized masses to cystic masses containing several ounces. They are usually single but may be multiple and the larger ones may be multilocular owing to pericystic adhesions and bands. They are mostly extravaginal but may be intravaginal and may simulate hydrocele. Rupture of an intravaginal cyst explains the occasional findings of spermatozoa in hydrocele fluid. They contain a milky, alkaline or neutral fluid which contains no albumin and has a low specific gravity (1.002 to 1.006). Microscopically there are varying numbers

of active or inactive spermatozoa depending on the cystic connection with an active tubule.

Spermatocele is commonly found on routine physical examination unknown to the bearer but it may have been noticed as a growing mass at the top of the testicle which is usually pushed downward and forward. Owing to the size and weight of the cyst there may be a dragging sensation in the testicle and spermatic cord.

On palpation there is a rounded heart-shaped fluctuating mass connected with the upper pole of the testicle at its union with the epididymis. With a large soft cyst these relations may not be apparent. A spermatocele usually transilluminates and the diagnosis can be made with certainty only by aspiration. The fluid obtained usually distinguishes it from hydrocele but both lesions are not uncommonly found together. Neoplasms and tuberculous epididymitis must always be kept in mind as possibilities.

Treatment.—A small or moderate-sized spermatocele usually requires no treatment. A large cyst producing local symptoms or mechanical interference should be removed surgically. It is technically possible sometimes to free the cyst from its pedicle and remove it again if it may be necessary to open the cyst and remove the lining completely. This may be done by cauterization. When multiple small cysts are found together with a large cyst a partial upper pole epididymectomy is indicated. Partial epididymectomies may be necessary also when dense adhesions are encountered. Injection treatment of spermatocele is valueless.

CRYPTORCHIDISM

(Undescended Testicle)

Incidence.—Imperfect descent of the testicle during the first few months of extra-uterine life is common (14 per cent according to some statistics). In many cases however the descent is spontaneous during the first year. Undescended testicle is variously estimated to occur in from 0.1 to 0.2 per cent of males. Neither side appears more

susceptible than the other but bilateral involvement is rare.

The descent of the testicle may be stopped at any stage. Thus there may be the following types:

1 Abdominal type (does not enter the inguinal canal).

2 Inguinal type (arrested in the inguinal canal).

3 Subinguinal type (arrested just below the external ring).

Rarely the testicle may be movable and may change from one type to another. The testicle may migrate to the pelvis, abdominal wall, penis or perineum or even to the other side of the scrotal sac (inversion of the testicle).

The commonly mentioned theoretical causes of this condition are shortness of the blood supply or of the vas deferens, an abnormally large testicle or epididymis, peritoneal adhesions, deficiency or absence of scrotal attachments of the gubernaculum and an improperly developed inguinal canal.

There are no symptoms especially referable to this condition and the diagnosis is apparent with the finding of the empty scrotal sac, the rare conditions of anorchism and ectopia being kept in mind. Acute epididymitis in such an organ however may be difficult to differentiate from strangulated hernia or torsion of the cord. Immediate operation is indicated regardless of the type of lesion.

An undescended testicle of any type is unfavorably affected by its abnormal position. It has been shown experimentally that because the temperature of the abdominal wall and its cavity is higher than that of the scrotum an undescended testicle is usually sterile. Being relatively immobile it is more subject to trauma and varying degrees of atrophy from anemia and its increased susceptibility to neoplasms and torsion has been definitely established. The inguinal and subinguinal types are frequently associated with hernia.

Treatment.—An undescended testicle is seriously affected if allowed to remain as such and operation is therefore indicated.

Spontaneous descent rarely occurs after the first six years of life. It is generally agreed that in cases of undescended testicle or chidopexy should be performed between the ages of six and nine years when the stric-

tures are not too small cooperation of the patient may be had and the dangers of serious degenerative changes have not yet occurred. No operation should be performed for an intra-abdominal testis (Fraser).

Orchidectomy is indicated only if a neoplasm is present or if complete destruction from trauma or infection has occurred.

Operative Treatment—Bevan has shown that shortness of the vascular supply and not shortness of the vas deferens prevents the placing of the testicle into the scrotum. Lengthening the blood supply consists of dissecting away the fibrous attachments which retain the vessels in their tortuous position producing straight vessels from the internal ring to the testicle. Further length may be obtained by freeing the vessels from the lateral and posterior wall of the peritoneum. Cutting the main blood supply and depending on the deferential artery which follows the vas deferens for the blood supply was frequently practiced formerly but atrophy of the testicle resulted too frequently to warrant the procedure.

Anchoring the testicle to the bottom of the scrotum and other modifications of the procedure are not deemed necessary.

An associated hernia should be dealt with according to its type; however, a standard hernia closure should be made without the presence of this complication.

Many types of operations have been presented and reported as successful and any one of them which includes the fundamental requisites is certain to be successful in the great majority of cases.

Medical Management—There are numerous reports in the literature dealing with the value of gonadotropic substances in producing spontaneous descent of undescended testicles. These reports are most conflicting and confusing. While descent does occur sometimes under this management many valued opinions indicate that this happens only when the testicles would have descended without any management. The presence of firm adhesions encountered at operation in properly selected cases as regards the age of the patient and the local position of the testicle tends to confirm the correctness of this opinion. Some reports have been made of necrosis of the testicle following hormone treatment.

VARICOCELE

Varicocele is a condition characterized by dilatation elongation and tortuosity of the spermatic veins. In advanced cases the deferential and cremasteric veins are sometimes involved.

Idiopathic varicocele is a common condition in young men. The left side is most commonly affected presumably because of the poorer venous flow resulting from the right angle insertion of the left spermatic vein into the renal vein. Bilateral varicocele is rare and right-sided involvement alone rarely, if ever occurs.

Symptoms—Varicocele usually produces no symptoms unless attention is directed toward the lesion in a neurotic person. A dragging pain along the cord and in the testis does occur as well as certain obscure low back pains. Mental symptoms of varying degree may appear depending on the mental stability of the patient.

Diagnosis—Examination reveals a low hanging scrotum containing an irregular elongated mass above the testicle. The testicle is frequently soft and small. When the patient is lying down the mass may completely disappear.

Treatment—In the great majority of cases a varicocele requires no treatment. The demands of industry for operations before men will be employed have increased the number of operations needlessly. Under no circumstances should a highly neurotic person be subjected to operation unless there is a well advanced lesion. A snug suspension often suffices even in apparently well advanced cases. Mental treatment is often more valuable than an operation and reassurance of the benign nature of the condition should always be given regardless of the

local management. Operative management should consist of open operation and not subcutaneous ligation. The enlarged veins should be carefully dissected away from the remainder of the cord, starting 1 inch above the testicle and extending upward to just below the external ring. The veins are thoroughly ligated at each end and the intervening strip is removed by cutting. The venous stumps are brought together and held by ligature for support of the testicle. Atro-

phy of the testicle may result, and secondary hydrocele occurs more commonly. To obviate this second complication, a regular hydrocele operation of the tunica vaginalis has been carried out at the time the veins were removed.

on voiding and usually a slight leukorrhea. Since these sensations are not uncommon they may cause no apprehension and may disappear within four or five days. In severe cases these disturbances are more marked. It is rare however for a woman to be incapacitated by acute gonorrhea of the external genitalia.

Chronic gonorrhea of these organs also may be symptomless unless an abscess or cyst forms in Skene's or Bartholin's glands or the leukorrhea or burning at urination becomes disturbing.

Diagnosis—The diagnosis is made by finding the lesions and by demonstrating the gonococcus in the secretions by stain or culture. In acute cases this is usually easy; in chronic infections specificity may be difficult to establish. The discharge may contain many secondary invaders (colon bacillus, streptococcus and staphylococcus) that the gonococcus may be submerged. Conclusions must then be based on the clinical picture as a whole.

Treatment—During the acute stage it is unwise to try any local measures but cleanliness. Efforts to treat the red, swollen urethra will almost surely cause cystitis and local treatment of the acutely infected cervix is apt to produce salpingitis and peritonitis. Local cleanliness is necessary and accomplished by soap and water to the external genitalia or external perineal irrigations (not vaginal douches) of potassium permanganate solution 1:6000 two or three times daily.

During the acute stage hygienic measures must be employed to protect other members of the household and the patient herself especially her eyes and to prevent the infection from spreading to the internal genitourinary apparatus and peritoneum. Fortunately since chemotherapy has been introduced efficient curative therapy is also possible during the acute phase.

For hygienic purposes the patient is isolated as far as lavatory and bathroom facilities are concerned. Little girls are scrupulously prevented from using any bathroom facilities that are used by an infected person. To protect the patient's eyes from infection the hands must be kept away from her face. Coitus is forbidden.

Medical therapy consists of rest in bed

forcing water (3000 cc daily) and chemical therapy. Rest in bed is not always essential but will shorten the disease and may prevent its further extension. Gonorrhea is susceptible to the sulfonamides and they are used in ordinary doses (sulfathiazole 4 to 6 Gm daily) with usual precautions. Penicillin is also apparently effective against the gonococcus but is difficult to use outside of a hospital. Sulfonamides should be continued at least a week or ten days. By this time the local infection should be either eliminated or well under control. Smears and cultures are taken from the cervix and urethra at the end of this treatment and must be repeated at monthly intervals for two or three months.

In the chronic stage chemotherapy is not so effective and measures such as douches and local heat are merely palliative. It may be impossible to find the gonococcus in old lesions in Bartholin's glands, the cervix or Skene's glands but the frequency of exacerbations and recurrent symptoms indicate the persistence of infection whether due to the gonococcus or some other secondary invader. In these closed lesions without adequate external drainage the disease can best be eliminated by excision of the infected Bartholin's gland, excision or cauterization and destruction of the periurethral gland and cauterization of the cervix. This cauterization must be thorough, opening up and destroying all infected glands. The cauterized cervix or urethra should be dressed every week, the exposed tissues being saturated with some strong antiseptic such as tincture of iodine, 20 per cent silver nitrate or 20 per cent mercurochrome solution. It is only by such thorough measures that the deep foci of gonorrhea may at times be eliminated.

The Internal Genitalia—Pathology—In acute gonorrheal salpingitis the entire tube becomes red and swollen and exudes pus which contains gonococci. As the acute process subsides the fimbria usually closes and at various points the tube presents nodular thickening. It adheres to surrounding structures. If the secretions within the closed tube increase the tube distends its walls become thick and there develops a hard, sensitive convoluted mass—a pyosalpinx. In old cases the fluid may be watery—a hydrosalpinx. Both tubes are usually involved. Thus gonorrhea often results in

some permanent damage, such as closed tubes nodular thickening adhesions pyosalpinx or hydrosalpinx

The usual ovarian lesion is perioophoritis a superficial infection of the ovarian capsule and may produce permanent thickening of the tunica albuginea and adhesions thus interfering with normal ovulation. The gonococcus rarely invades the ovarian stroma unless it finds a portal of entry in a fresh corpus luteum or graafian follicle. This may cause an ovarian or tubo-ovarian abscess. Salpingitis is usually accompanied by pelvic peritonitis.

Clinical Characteristics—Gonorrheal salpingitis if treated intelligently should rarely be fatal. Death may occur from peritonitis a neglected pelvic abscess intestinal obstruction or an operative accident.

The usual symptoms are pain in the pelvis sacral backache leukorrhea dysuria menorrhagia dysmenorrhea malaise and occasionally nausea and vomiting. Usually fever slight elevation of the pulse suprapubic tenderness and on bimanual palpation nontenderness in the pelvis are noted. In acute cases there are usually no masses but they may be found later.

The course is usually benign. Within ten days the infection usually subsides and localizes the treatment being rest in bed in Fowler's position douches of a gallon of hot permanganate solution (1:6000 twice daily) icebags to the abdomen chemotherapy and sedatives as needed.

After recovery from the acute attack the subsequent course varies depending upon the persistence of the remaining loci of infection in the patient or reinfection from external sources. Although symptomatically well the patient may harbor a chronic infection in the external genitalia or the fallopian tubes which may cause exacerbations at any time. Such exacerbations are particularly liable to develop after a menstrual period. Hence for several months after recovery from an attack of acute gonorrhea chemotherapy should be used for a few days after every menstrual period prophylactically.

The damage to the tubes and ovaries is cumulative depending upon the number of reinfections or exacerbations. In neglected cases, the tubes are hopelessly destroyed

and at times also the ovaries. Pelvic abscess with secondary invaders and peritonitis may develop often with fatal results.

Treatment—The treatment of acute salpingitis has been outlined—rest in bed forcing water icebags to the lower part of the abdomen hot (gallon) douches sedatives and chemotherapy. Almost invariably resolution is prompt. In reinfections or subsequent recurrences the treatment is similar. Usually acute exacerbations will quiet down but as the tubal damage increases masses persist even after the symptoms disappear. In general in recurrent salpingitis the safest therapy is surgical—bilateral salpingectomy. Healthy structures are not removed. In neglected cases in which the ovaries have been practically destroyed oophorectomy and hysterectomy may be necessary. Surgical treatment is best postponed till the acute exacerbations have subsided.

Differential Diagnosis—It is most important to differentiate acute salpingitis from acute appendicitis. Acute appendicitis demands immediate operation. Acute salpingitis rarely does. The proper diagnosis is of fundamental importance.

Salpingitis is indicated by a history of the primary infection dysuria vaginal burning leukorrhea and perhaps menstrual irregularity. The tenderness may also be more diffuse and suprapubic especially in the end of sac of Douglas and the pelvic floor. The outlet is marred and the presence of gonorrhea of the external genitalia is strong presumptive evidence.

Appendicitis is indicated by gastrointestinal disturbance usually nausea and vomiting generalized abdominal pain and later localized pain at McBurney's point. Muscle spasm and tenderness are usually more sharply localized in appendicitis and rebound tenderness referred to McBurney's point suggests appendicitis.

In both salpingitis and appendicitis the acute attack may start during menstruation. In both leukocytosis with an increase in the polymorphonuclear leukocytes is accompanied by fever and acceleration of the pulse. A mass is rarely felt in either case during the early stages. If appendicitis can not be excluded the abdomen should be opened rather than allow an appendix to rupture.

It is sometimes difficult to distinguish acute salpingitis from extrauterine pregnancies. Ovarian cyst with a twisted pedicle or a variety of acute pelvic conditions. In the chronic stage proosalpinx may be confused with an ovarian tumor corpus luteum cyst or endometriosis.

Gonorrhea in Children—In girls before puberty gonorrheal infections are usually limited to the vagina and cervix salpingitis peritonitis and metastatic lesions are rare. In the vagina and cervix the infection invades not only the mucosa but also the deep submucosal tissues including probably also the cervical canal and glands. The reason for this peculiar localization is the thinness of the vaginal epithelium before puberty and its low resistance to any infection. The child's vaginal epithelium attains full development at puberty due to stimulation by the growth hormone estrin. This same sexual development can be brought about precociously by the administration of estrogenic substances. In rodents this vaginal response to estrin is used as a test for the presence of estrogenic substances.

This physiological fact is also the basis of the modern treatment of gonococcal vaginitis in children. It was first used by Lewis in 1913. If in children with gonococcal vaginitis one enlarges the vaginal epithelium to the thick mature resistant type the infection usually disappears promptly without any additional therapy. Estrogens are used daily in the form of vaginal suppositories which contain stilbestrol aminotin or some other similar estrogenic material. By vaginal smears one follows the progress of the vaginal development until the smear finally shows only angular cornified epithelial cells without any immature cells pus cells or gonococci. Cultures are also advisable. This change is usually complete in ten to fourteen days. To favor the permanent elimination of gonococci estrogenic vaginal suppositories are given for a week or ten days longer perhaps less frequently. Also follow up studies are repeated at intervals of one month to be sure that the child is well.

In the majority of cases this results in permanent cure. But the gonococcus is a persistent organism and recurrences or reinfections occur in perhaps 10 or 15 per cent. In these cases it is wise to inspect the vagina

with a Kelly tubular cystoscope. Occasionally foreign bodies are found or foci that should be treated locally by the application of mercurochrome acriflavine or silver nitrate.

Sulfonamides have also been used usually with good results. But here too recurrences have been noted and local therapy may be necessary. An antiseptic solution can be applied with a medicine dropper which is inserted into the vagina.

TUBERCULOSIS

Until thirty years ago pelvic tuberculosis was thought to be rare. Now it is known that perhaps 7 per cent of all pelvic infections that require operation are tuberculous.

Pathology—This phase has been studied carefully by Hegar (1880) Schlimpert (1914) Greenberg (1921) and others. In many fundamental particulars it differs strikingly from gonorrhea.

Pelvic tuberculosis is a local manifestation of a systemic disease the primary focus of which may be the lung the intestinal tract or the lymph glands in the neck or mediastinum. In women the reproductive organs rank fourth in frequency the lungs intestinal tract and peritoneum being more often involved.

Tuberculosis and gonorrhea differ as to the localization of the pelvic lesions. In gonorrhea the external genitals the urethra Skene's glands Bartholin's glands the vagina and cervix are always involved to a greater or less extent. In tuberculosis however these organs are hardly ever involved as the writer pointed out in 1921. Tuberculosis attacks the fallopian tubes in almost every case the endometrium in three fourths and the ovaries in one third of the cases. Tuberculosis is therefore a disease of the internal reproductive organs.

Tuberculosis is usually a progressive disease and is often more destructive than gonorrhea. Pregnancy is rare after tuberculous salpingitis and is usually disastrous. Gonorrhea starts on the mucous membrane affecting the deeper structures secondarily. Tuberculosis being metastatic affects every part of the organ causing multiple tubercles which coalesce erode and form hard abscesses of various sizes.

General peritonitis occurs more commonly with tuberculosis than with gonorrhea. Whether independently or not, tuberculous peritonitis and tuberculous salpingitis occur with almost the same frequency and very often are coexistent. The peritoneal symptoms of tuberculous salpingitis are often the outstanding characteristics of the disease.

Clinical Picture—For these reasons tuberculous pelvic infections are potentially more serious than gonorrheal infections but in many cases the course is relatively mild with practically no physical incapacity and with quiet resolution. Laparotomy later discloses healed tubercles scattered over the surface of the reproductive organs and peritoneum. In such instances the disturbance was probably a superficial tuberculous peritonitis without salpingitis or endometritis. In other instances persistent leukorrhea may be the only symptom and curettage may reveal unsuspected tuberculous endometritis.

The onset is usually vague, a common antecedent being a miscarriage or normal pregnancy. It occurs most frequently in the period of sexual activity. The symptoms are usually those of a chronic pelvic infection and the clinical picture is rarely characteristic enough to suggest tuberculosis. In some instances the diagnosis cannot be made at operation, microscopic examination being required. At times a diagnosis of malaria or typhoid fever has been made.

The constitutional symptoms are marked chiefly by their persistence and indefiniteness—malaise, anorexia, recurring fever in digestion and loss of weight. The local symptoms may suggest gonorrhea, ovarian tumor, malignancy or appendicitis but rarely tuberculosis. The resemblance at any time depends on the stage of the disease.

During the acute febrile stage when the pelvic organs are edematous and swollen the peritoneum is covered with milium tubercles and free fluid is present the diagnosis may be fairly easy if the pelvic masses are palpable. Certain medical conditions which might produce a similar abdominal picture must be ruled out. If pelvic pain, menstrual disturbances, leukorrhea, sterility and pelvic masses are present and if gonorrhea can be eliminated the diagnosis of tuberculosis may be ventured. If the patient is a virgin who has had other tuberculous le-

sions the likelihood of pelvic tuberculosis is increased.

After absorption of the free fluid and subsidence of fever the only residuum may be adhesions, healed tubercles, closed tubes and dormant lesions in the pelvic organs and lymph glands. During this afebrile state, preoperative recognition of the condition is practically impossible. The diagnosis is often made when the abdomen is opened for some unrelated indication. It is during this dormant and afebrile stage that the best surgical results are obtained.

The third or massive stage is characterized by the presence of pelvic and abdominal masses and dense adhesions and is the most serious form of the disease. The intestine, omentum, bladder, rectum and reproductive organ are inextricably tied up in inflammatory masses. Cold abscesses developed from broken down cascating tubercles form masses between loops of intestine and may produce intestinal fistulas. Cascating glands add to the confusing picture. Free fluid may be present.

In this stage the patient is really sick. Loss in weight, digestive disturbances, fever, nausea, vomiting, obstinate constipation, abdominal pain and distention are common. The patient may feel an abdominal mass. Menstrual disturbances, leukorrhea, amenorrhea and pelvic pain are common.

Under these circumstances every conceivable diagnosis is possible. The history or the finding of healed tuberculosis elsewhere may suggest the diagnosis. Diagnoses have included all forms of abdominal and pelvic pathologic conditions, especially carcinoma of the ovary and pelvic tumors with infection.

Treatment—In this stage the operative treatment is unsatisfactory and may be followed by serious postoperative sequelae—peritonitis, obstruction, hemorrhage and fistulas. Because of the raw areas and oozing surfaces the operator is often tempted to institute drainage but experience has shown that abdominal drainage invites rather than prevents trouble.

Sanatorium treatment and prolonged medical care have a definite place in the treatment of pelvic tuberculosis. In general surgical intervention is advisable only when the disease is limited to the pelvis or abdo-

men Fever is often an indication that the tuberculous process is active and operation may eliminate it generally. Consequently the best surgical results are obtained when the process is inactive. In some cases the diagnosis is in doubt and delay inadvisable. Hence many operations are necessarily performed under the most unfavorable circumstances.

In general three fourths of the patients at Johns Hopkins Hospital have improved very satisfactorily after surgical removal of tuberculous pelvic organs. After the first year the results are better because tuberculous dissemination usually develops within that time if it is to appear at all. The chief advantage of surgical treatment is that it shortens hospitalization in every case; however prolonged medical supervision is essential.

PUERPERAL INFECTIONS

Only a brief resume of the surgical aspects of puerperal infections will be given here.

The story of puerperal fever goes back to the beginning of medicine. Although a tremendous morbidity and mortality had stigmatized maternity hospitals for centuries and epidemics of virulent childbed sepsis had occurred regularly, the cause of the fever was entirely a mystery until Oliver Wendell Holmes (1819) and Semmelweis (1847) proved that it was a wound contamination and that the causative agent was almost invariably transmitted by the doctor or midwife. They knew nothing about bacteria, but their pathologic concept was as sound as it was revolutionary. Their ideas were not acceptable to their professional contemporaries and puerperal sepsis continued its ravages.

Since that time the sciences of bacteriology and pathology have yielded compelling proof of the theories of Holmes and Semmelweis. Nevertheless the danger of puerperal infection still makes normal childbirth as hazardous as some major surgical operations. On the basis of a tremendous experience in private and institutional obstetrics DeLee (1913) stated that puerperal sepsis kills one in every four hundred women delivered of full term children and makes incurable in valid of at least ten times that number. The mortality from criminal abortion is an ever increasing and forbidding figure. This entire

situation is a challenge to modern obstetrics and until healthy young women can have their babies in comparative safety the biggest problem in obstetrics remains unsolved.

Acute Puerperal Infections.—An oral temperature above 100° F. after delivery usually indicates that infection is present. It may be mild, severe or fatal and it may involve any part of the reproductive system. It may have its origin in a vaginal or perineal tear, a cervical laceration or the placental site. Depending on the resistance of the patient and the virulence of the organism the infection may remain localized or may spread rapidly to surrounding structures producing cellulitis, lymphangitis, phlebitis, abscess or peritonitis. It may invade the blood stream and cause distant metastatic abscesses.

During the acute phase efforts should be made to cause the infection to localize. For ex. bodies such as infected placental tissue should be removed carefully without breaking down the protecting leukocytic wall or opening new vascular spaces. Strict cleanliness is attained by antiseptic douches of a gallon of hot solution of potassium permanganate (1:1000). Peritonitis and sepsis often terminate fatally. Their treatment is beyond the scope of this chapter, but it is well to note in passing that the surgical treatment of peritonitis has been revolutionized in the last few years and that results have improved.

Every puerperal infection regardless of its location or apparent insignificance is potentially dangerous. These cases require the keenest observation and the most careful handling. Regard for the finest details makes the difference between success and failure. Surgical intervention is resorted to only when unavoidable, for example to drain an abscess or remove infected material from the uterine cavity. Even minor instrumentation and examinations must be performed with meticulous care. The writer is not convinced that it is advisable to ligate the femoral or iliac veins in a case of infected thrombosis or to perform a hysterectomy during an acute puerperal sepsis.

Chronic Puerperal Infection.—If the patient survives the stage of acute sepsis she may or may not suffer permanent disability. In general the more severe the infection

being learned from cases in which there is recurrence after the use of the sulfonamides.

The method of administration is given in the current literature as well as the dangers that attend use of sulfonamides. These drugs should never be used unless the physician sees the patient often and is alert to the many complications that develop in a definite number of cases.

Every year new sulfonamides are being introduced which vary in their toxicity. In general all sulfonamides must be used with care. Most cases of acute gonorrhea yield to them although it has been indicated chemotherapy has definite limitations in all infections.

In cases that are resistant to sulfonamides penicillin is at times effective. One cannot yet finally appraise its value in gonorrhea because time is an essential criterion in determining the result. Furthermore because of technical difficulties penicillin has not been used very widely. In using penicillin as with sulfonamides one must not expect the impossible for as Herrell has said

penicillin therapy is no substitute for sound medical and surgical judgment in the treatment of bacterial infections and the treatment of gonorrhea still requires all the combined skills of the physician and surgeon.

earl point of view a more descriptive term. The designation leiomyoma is occasionally used.

Incidence.—Myomas are found very frequently in the uteri of women in the fourth and fifth decades, being found in about 20 per cent of women over thirty-five. They are much less frequent in women between twenty and thirty years of age but even then are often found. Many of the tumors which are discovered in the thirties began in the twenties. It is not uncommon to see a woman in middle life with a myomatous growth which she has been aware of for many years. New growths do not appear after the menopause but previously existing tumors may slowly increase in size or undergo degenerative processes which may lead to enlargement and render intervention necessary. In clinic in which many colored patients are treated the incidence is greater as there appears to be a racial predisposition to myoma.

Structure.—Myomas are made up of a mixture of smooth muscle and fibrous tissue the proportion varying in different tumors. The cut surface of the tumor varies with the proportion of these two tissue elements being firm and pale when it is predominantly fibrous and softer and of a pinkish hue when a considerable proportion of muscle is found.

Location.—Myomas are classified according to their relationship to the uterine wall into (1) *interstitial* (intramural), (2) *subserous* and (3) *submucous*. All tumors originate in the myometrium and become subserous or submucous as growth proceeds.

A tumor which grows outward comes to lie under the serosa and is known as a *subserous myoma*. Such a tumor may produce a mass on the surface of the uterus and possibly as it continues to grow become pedunculated. If it grows sufficiently large and its pedicle finally does not afford it an adequate blood supply it may develop a secondary blood supply from other sources usually the omentum. Torsion of the pedicle of a subserous fibroid may occur necessitating immediate intervention.

A tumor which lies near the surface in the lateral wall of the uterus may pass between the leaves of the broad ligament as it grows outward. These tumors are known as *intraligamentary myomas*. They may attain considerable size and sometimes produce pres-

the greater the likelihood that it will result in incapacity. The permanent damage consists of abdominal and pelvic adhesions, chronic infection of the tubes, endometrium, cervix and parametrium recurring abscesses in the pelvis or broad ligaments and metastatic infections such as arthritis. The streptococcus is the most frequent cause.

The characteristic picture of an old streptococcal puerperal infection consists of pelvic adhesions with open fallopian tubes. This is not like gonorrhea or tuberculosis in which the fundamental lesion is salpingitis and in which tubal closure is practically invariable. In streptococcal puerperal infection the process is primarily an endometritis, cellulitis or peritonitis and the tubes are involved only secondarily. This explains the frequent possibility of pregnancy after puerperal peritonitis.

Endometritis and cervicitis may persist indefinitely causing menstrual disturbances, leukorrhea, pelvic pain and backache. The writer has isolated the streptococcus in pure culture from the endometrium three years after complete symptomatic recovery from puerperal peritonitis, the indication for the examination being the development of severe polyarthritis. Such latent infections in the pelvis are a continual menace; they may flare up at any time, especially after curettage, cervical cauterization or miscarriage and they are always likely foci of metastatic infection.

At times it is very difficult to localize a puerperal infection, particularly in the extraperitoneal space of Retzius or between the upper layers of the broad ligament near the pelvic wall. In these locations infections have remained undetected for months causing fever, obscure pelvic pain and invalidism. Obesity greatly increases the difficulty of making a diagnosis. Eventually, however, careful palpation usually reveals induration along Poupart's ligament or deep in the suprapubic region and on bimanual examination a corresponding sensitive area of induration or mass is found. Such purulent collections must be opened extraperitoneally just above Poupart's ligament or above the pubis. Since they are almost always due to the streptococcus and are extraperitoneal it is vital that the peritoneum should not be opened.

The usual case marked by pelvic adhesions, uterine misplacement, cervicitis and perineal laceration is a vicious mixture of the mechanical injuries caused by labor and the damage done by a puerperal infection. The treatment is a complicated major gynecological problem. The nature of the operation depends on the age of the patient and the condition of the pelvic organs. In general the diseased structures should be removed and the pelvis should be restored to such a condition that other organs, though perhaps slightly involved, may again become healthy. Mechanical faults should be corrected. In young women the treatment should be conservative if possible. In older women near the menopause, however, questionable organs should be removed without hesitation.

In general the surgical treatment of chronic puerperal infection should be conservative for it is always fraught with danger. The longer operation can be deferred the better. Even minor instrumentation may reactivate an infection which for years has been dormant.

CHEMOTHERAPY IN PELVIC INFECTIONS

The treatment of pelvic infections has been greatly facilitated by the sulfonamides. They are particularly useful in those infections which are due to the gonococcus and the beta hemolytic streptococcus. They are therefore of wide use in gynecological and puerperal infections.

Sulfadiazine, sulfathiazole and sulfamida are effective in gynecological infections but there are certain definite limitations to their use. Thus in chronic infections which are enclosed in pockets such as chronic salpingitis, tubo-ovarian infection and deep infections in the perineal and perivaginal glands or cervix these products are useless except for palliation. These deep closed foci must be eradicated surgically in order to eliminate the infection.

The sulfonamides are useful however in acute open infections such as mark the onset of these diseases. In acute salpingitis, acute pelvic peritonitis and other acute infectious processes the sulfonamides are usually effective, shortening the course of the disease. But one cannot assume that relief of symptoms means cure of the infection as is

being learned from cases in which there is recurrence after the use of the sulfonamides.

The method of administration is given in the current literature as well as the dangers that attend use of sulfonamides. These drugs should never be used unless the physician sees the patient often and is alert to the many complications that develop in a definite number of cases.

Every year new sulfonamides are being introduced which vary in their toxicity. In general all sulfonamides must be used with care. Most cases of acute gonorrhea yield to them although as has been indicated chemotherapy has definite limitations in all infections.

In cases that are resistant to sulfonamides penicillin is at times effective. One cannot yet finally appraise its value in gonorrhea because time is an essential criterion in determining the result. Furthermore because of technical difficulties penicillin has not been used very widely. In using penicillin as with sulfonamides one must not expect the impossible for as Herrell has said penicillin therapy is no substitute for sound medical and surgical judgment in the treatment of bacterial infections and the treatment of gonorrhea still requires all the combined skills of the physician and surgeon.

TUMORS OF THE UTERUS

I. BENIGN TUMORS

MYOMA

(Fibroid Fibromyoma Leiomyoma)

The term myoma is preferable although the word fibroid is in common use in this country. Fibromyoma is from the anatomical

point of view a more descriptive term. The designation leiomyoma is occasionally used.

Incidence.—Myomas are found very frequently in the uteri of women in the fourth and fifth decades being found in about 20 per cent of women over thirty-five. They are much less frequent in women between twenty and thirty years of age but even then are often found. Many of the tumors which are discovered in the thirties began in the twenties. It is not uncommon to see a woman in middle life with a myomatous growth which she has been aware of for many years. New growths do not appear after the menopause but previously existing tumors may slowly increase in size or undergo degenerative processes which may lead to enlargement and render intervention necessary. In clinics in which many colored patients are treated the incidence is greater as there appears to be a racial predisposition to myoma.

Structure.—Myomas are made up of a mixture of smooth muscle and fibrous tissue the proportion varying in different tumors. The cut surface of the tumor varies with the proportion of these two tissue elements being firm and pale when it is predominantly fibrous and softer and of a pinkish hue when a considerable proportion of muscle is found.

Location.—Myomas are classified according to their relationship to the uterine wall into (1) *interstitial* (intramural), (2) *subserous* and (3) *submucous*. All tumors originate in the myometrium and become subserous or submucous as growth proceeds.

A tumor which grows outward comes to lie under the serosa and is known as a *subserous myoma*. Such a tumor may produce a mass on the surface of the uterus and possibly as it continues to grow become pedunculated. If it grows sufficiently large and its pedicle finally does not afford it an adequate blood supply it may develop a secondary blood supply from other sources usually the omentum. Torsion of the pedicle of a subserous fibroid may occur necessitating immediate intervention.

A tumor which lies near the surface in the lateral wall of the uterus may pass between the leaves of the broad ligament as it grows outward. These tumors are known as *intra-ligamentary myomas*. They may attain considerable size and sometimes produce pres-

oma to be one to forty. Stout believes that the great majority of sarcomas begin in fibromatous uteri.

Symptoms.—Frequently a woman is found to have one or more myomas in the uterus which have caused no inconvenience whatever. Symptoms are dependent far more on the location of the tumor in the uterus and on its relationship to the uterine canal than on its size. A subserous tumor of considerable size in the fundus may cause no trouble while a smaller one directly under the mucosa may be associated with bleeding.

The most common symptom is bleeding but all fibroids do not bleed. Large tumors are often seen which have caused no loss of blood. Submucous tumors are most frequently the cause of bleeding usually menorrhagic in character due to the escape in excess in the blood content of the uterus at menstruation and to the fact that the delicate reticulum of vessels under the endometrium which lies over the tumor is broken by the contraction of the uterus as it expels the menstrual blood. Pressure on the endometrium by the tumor itself probably aids this process. As the myoma grows the bleeding period may become longer, so that the part of the monthly cycle which is free from bleeding may become quite short. Again infected necrotic submucous tumors may produce severe metrorrhagia. The menorrhagia accompanying myoma may cause severe secondary anemia. In the menopausal years dysfunctional bleeding is common. In many cases of this sort small myomas may be found but they may play no part in the production of the bleeding.

Pain may be felt in widely varying degree. There may be no sensation at all, only a feeling of mild discomfort or pain may be moderate or very severe. When there are heavy masses a sense of weight may be experienced and very large tumors may interfere with bodily functions producing respiratory difficulty or disturbance of the digestive tract.

The bladder will withstand much distention. So long as its ability to contain a normal amount of urine and to empty itself is not disturbed no vesical symptoms may appear. When these are interfered with distress is felt. Discomfort caused by pressure

backward on the rectum is rare. A tumor of moderate size in the lower uterine segment will produce more pain than a larger one in the upper part of the uterus as in the latter case far more room is found for expansion. The attempts of the uterus to expel a pedunculated submucous tumor may cause cramping pains and the torsion of a pedunculated subserous growth may produce agonizing suffering.

Diagnosis.—Differentiation must be made from pregnancy, inflammatory masses, ovarian neoplasms, endometriosis and in the case of small tumors on the posterior wall retrodisplacement. Any of these may be found together with myoma. If a mass is felt above the symphysis it is usually either a myoma or a pregnancy. A soft symmetrical myoma may simulate pregnancy closely. Amenorrhoea accompanies the latter. If necessary the Ashheim-Zondek test will usually distinguish between them. An irregular firm mass is usually a myoma. Ovarian cysts especially if they are tense and adherent may be confused with myomas. Motion transmitted from the abdominal hand on manual examination to the vaginal finger speaks for a uterine tumor. Submucous tumors may be difficult to recognize by palpation as the uterus may be but little enlarged and the symmetry but slightly altered.

Treatment.—From the therapeutic viewpoint myomas may be divided into three classes: (1) those which need no treatment; (2) those which may be irradiated and (3) those which should be removed surgically.

There are many myomas which need no treatment. Small symptomless tumors may be left alone but those from which symptoms arise need some form of treatment. Small subserous growths may be quite innocuous and may remain so for long periods of time or permanently. A tumor of moderate size at the fundus may be quite harmless while one of the same size in the lower uterine segment owing to the limited space surrounding it may cause serious trouble. When an expectant course is decided on the woman should be counselled that reexamination at intervals should be carried out in order that changes in size of the growth may not escape attention.

A limited number of myomas may be

managed by irradiation radium being preferable. The cases must be carefully chosen. Young women should not be irradiated since the dosage that is necessary to control bleeding is sufficient to destroy ovarian activity. If intervention is needful in these cases operation is better. Irradiation is best

which may be produced in these growths. Previous operation or pelvic inflammation which may have left adhesions renders irradiation unwise since a loop or loops of intestine may be immobilized in such a way as to hold it within range of the radium rays for the entire period of treatment and seri-

Fig. 663.—Subtotal hysterectomy—author's technique. The broad ligaments are clamped the round ligament being included. The ligaments are divided. A figure of eight suture ligature controls the broad and round ligaments the middle loop of the suture preventing the center of the ligated structure from escaping. After the broad ligaments have been divided, the uterus and fallopian tube is divided. Downward dissection need not be carried far.

Fig. 664.—The uterus has been amputated at about the level of the internal os the excision being wedge shaped so as to facilitate closure. The uterine arteries are ligated with a suture ligature catching a little of the tissue of the cervix to avoid slipping. This is shown on the left of the drawing. It is tied under the forceps and is then tied a second time over the end of the forceps which is then removed. This doubly ligates the vessel.

restricted to women well over forty years. It is better not to irradiate tumors over the size of a three month pregnancy. Pelvic infection past or present excludes irradiation because of the danger of recrudescence of inflammation. The presence of ovarian neoplasms renders irradiation unwise because of the possible degenerative changes

ous injury to the intestinal wall may result. Submucous tumors and those which cause pain should be excluded.

If operation is contemplated the following procedures may be considered. I. Abdominal operations: (1) subtotal hysterectomy with or without excision of the adnexa, (2) total hysterectomy and (3) myomectomy.

II. Vaginal operations: (1) vaginal hysterectomy and (2) vaginal myomectomy.

The most useful and most frequently performed operation for the treatment of myoma is subtotal or supravaginal hysterectomy

is present or when the cervix is notably unhealthy. Recent publications indicate that the incidence of carcinoma in the retained cervical stump after subtotal hysterectomy is about 2 per cent. The stump sometimes

Fig 670—The cervical stump is closed by two or three anteroposterior sutures which do not include the peritoneum

Fig 671—Peritonization is begun by a suture which passes through the anterior peritoneal edge, the round ligament, the tube (or the infundibulopelvic ligament if the adnexa are removed) and the posterior peritoneum. When this is tied, the ligamentary stump is inverted and covered. The suture continues across to the opposite side. The opposite stump is similarly buried.

Fig 672—Peritonization is completed. The stumps of the broad and round ligaments are not fixed to the stump of the cervix unless this can be done without any tension. The ovaries are left movable and in approximately their normal location.

tomy. The ovaries should be preserved whenever possible. The younger the patient the greater is the importance of maintaining ovarian activity. Total hysterectomy should be done when cancer of the

causes leukorrhea which does not respond well to treatment. For both of these reasons, of late years, total hysterectomy has come to be more frequently employed in active gynecological clinics. Expert pelvic surgeons

can do the total operation as safely as the subtotal but this is not true of operators of lesser experience. Careful postoperative studies of large series of cases indicate that at least in the hands of the average operator the added risk of the more extended operation is greater than the danger of the development of cancer in the retained stump. When carcinoma appears soon after subtotal hysterectomy this usually means that malignant disease was overlooked at the time of operation. If carcinoma of the corpus is suspected the excised uterus should be opened for inspection before the abdomen is closed so that if carcinoma is revealed the cervix may be removed at once.

Vaginal hysterectomy is of use when the tumor is small particularly if plastic work also is to be done but it requires a greater degree of technical skill. Although a larger tumor may be removed vaginally by a surgeon skilled in this mode of approach the abdominal route is wiser if the growth is bulky.

A submucous pedunculated tumor which protrudes through the cervix into the vagina should be removed by vaginal myomectomy. These tumors are always infected and intervention should be as simple as possible. The pedicle should be located which as the cervix has dilated to allow the escape of the tumor is usually easy. It is then grasped with a clamp and divided and the tumor removed the clamp being allowed to remain for twenty-four hours. Sutures should not be used. If other myomas are present in the corpus operation for their removal should be deferred for several weeks. Operation is always hazardous if performed before the complete subsidence of the infection which accompanies a pedunculated growth that has escaped into the vagina. Failure to observe this precaution will subject the patient to grave danger.

Polyps

Polyps are growths which arise from the mucosa of the corpus or cervix and may be single or multiple. The term polypoid endometritis has been used to designate a condition characterized by the presence of many polyps in the corpus. Cervical polyps are usually preceded by long standing cervical endometritis. They may project

through the external os. The size may vary but they are usually small. Cervical polyps may become necrotic through interference with their blood supply. Malignant change is not common but does occur. Cervical polyps may grow rapidly during pregnancy.

Symptoms and Diagnosis.—Cervical polyps are readily seen through a speculum. They are smooth round red masses from 0.5 to 1 cm. in diameter presenting at the external os or protruding through it. More than one may be present at a time. Bleeding is a common symptom and is irregular and usually slight in amount. Exceptionally free bleeding may be present. No pain is felt.

Treatment.—A small polyp may be grasped as high as possible by a dressing forceps and twisted off. A larger one may be removed by a wire snare. If bleeding follows then packing may be needed. If the pedicle is visible it may be divided by the cautery. If a number of polyps are present the cautery may be used. If the endocervicitis remains other polyps may develop later. Permanent relief will follow the correction of the endocervicitis by means of plastic surgery.

ADENOMYOMA

An endometrial invasion of the uterine wall with accompanying muscular hyperplasia is now usually termed adenomyosis. It is produced by extension into the uterine wall of a growth of endometrium or by metaplasia of the stroma covering the corpus. Sampson believes the latter to be rare and that posterior adenomyosis at least is caused by the proliferation of endometrium which reaches the rectovaginal pouch through the tubes. The growth is usually small but may grow to the size of an orange. It is more often found in the posterior wall and may be found with myoma. Microscopically areas of typical endometrial tissue are found which show no evidence of menstrual activity and are surrounded by an area of cytogenic stroma.

The differential diagnosis from myoma is usually impossible to make. The most characteristic symptom is menstrual hemorrhage the bleeding being increased as to length and amount. Marked anemia may develop. The best treatment is hysterectomy. Radium is often ineffective.

II MALIGNANT TUMORS

CARCINOMA

Carcinoma of the Cervix—Carcinoma of the cervix is far more frequent than carcinoma of the corpus about 80 per cent of uterine carcinomas being found in the cervix. The tumor is usually found in younger patients than is corporeal carcinoma. Cullen found that 72 per cent of the patients in his series were between thirty-five and fifty-five. Under twenty years it is rare. Women who have borne children especially those who have had several labors show a marked predilection for cancer. Franklin's series for example showed only 3 per cent of nulliparae.

It is not established that carcinoma begins in the scar of an old laceration. It is certain however that an excited eroded irritated and profusely discharging cervix is far more frequently the seat of malignant disease than a healthy one. Plastic restoration of the diseased cervix or the healing of excision by the cautery reduces the danger of malignant disease. Improper technique in the use of either of these may cause stricture of the cervix.

Pathology—The simplest classification is that of Kuge-Verl which divides cervical carcinomas into two classes—carcinoma of the portio vaginalis and carcinoma of the cervix proper. The former arises from the visible vaginal portion of the cervix and the latter from the cervical canal between the external os and the upper limit of the cervix. Carcinoma of the portio vaginalis as a rule is of the squamous cell or epidermoid type while cervical cancer is adenocarcinomatous. In a far advanced growth it may be difficult to tell the point of origin of the tumor and even the microscopic appearance may not definitely indicate where the growth began. In some cases the two types of carcinoma may be combined. The squamous cell type is by far the more frequent.

Classifications as to the degree of malignancy based on the predominating cellular type have been made by Broders and Martzloff but their prognostic value is a matter of opinion. In estimating curability one must also consider the age of the patient the degree of advancement of the growth as evidenced by the visible growth the degree

of fixation of the uterus and the degree of the parametrial invasion.

Adenocarcinoma of the endocervix may reproduce the alveolar structure of the epithelium or the lumina of the alveoli may be filled by the ingrowing of cells.

As the cancer increases in size it tends to necrose on the surface and a breaking down of the superficial tissue occurs with crater formation. This may produce a watery discharge and a foul odor the result of the invasion of the necrotic area by the saprophytic microorganisms of the vagina. The necrotic process may erode the blood vessels of the cervix and produce bleeding. Frequently by the time that bleeding appears the growth has already progressed so far that hope of cure is small.

Extension of carcinoma of the portio vaginalis may occur to the adjacent vaginal wall. Extensive invasion anteriorly may ultimately produce a vesicovaginal fistula. Posterior progression may involve the rectum and produce a rectovaginal fistula. Lateral extension of the carcinoma may occur into the parametrium with eventually firm fixation of the uterus. A part at least of the early fixation may be due to the infection which is present in the necrotic masses and which may extend into the parametrium. Extension of cancer of the portio vaginalis occurs earlier and is more extensive than is the case in cancer of the corpus because the epidermoid type of cancer which is found in the portio vaginalis is a more rapidly growing type of carcinoma than the adenocarcinoma of the corpus. Lymphatic drainage from the cervix is more extensive than from the corpus.

Extension by invasion of contiguous tissue permits more extensive growth in cancers of the portio than in those of the corpus. Extension along epithelial surfaces is frequent in carcinoma of the portio. Cervical carcinoma may extend upward and involve the corpus usually by continuity after the entire extent of the cervix has been invaded. Extension may occur into the lymphatics of the pelvis and lower abdomen. Metastases may occur in the broad ligaments and compression of the ureter may be found in advanced cases with hydronephrosis and hydro-nephrosis. Obstruction of the cervical canal may produce a pyometra.

Symptoms—It is unfortunate that uterine carcinoma produces no early symptoms. Bleeding is usually the first sign which attracts attention and may be small in amount and intermenstrual. Increased flow which is always associated with the periods is not suggestive of cancer. Any irregular bleeding particularly in a woman in the fifth or sixth decennium should be regarded with suspicion. Bleeding which follows slight trauma such as digital examination, coitus or douching is suggestive but bleeding which comes on after the menopause is particularly suggestive. There are other causes which may produce postmenopausal bleeding but carcinoma must always be seriously considered. It is well to consider all cases in which bleeding occurs after the menopause has been well established as cancer until some less serious cause can be demonstrated. A discharge other than blood may appear which is usually watery and possibly foul but this is usually a late development of cancer.

Symptoms referable to the urinary tract are usually noted in late cases. If these are present when the patient is first seen the probability of cure is small. Loss of weight and anorexia are late manifestations.

Diagnosis—A late case with extensive cauliflower-like masses on the cervix extension on the neighboring vaginal mucosa and fixation of the uterus is easy of recognition. Bleeding at contact with the examining finger and friability of the mass are characteristic.

Ulceration is found in relatively early cases and may vary from a small localized lesion to a complete destruction of the cervix. In the latter event a large crater-like area may be found.

In order to obtain an increase in the number of cures the recognition of a greater number of cases must be made sufficiently early that the growth can be removed in its entirety.

only necrotic tissue may be secured. The cells in such a piece are so altered by necrosis that accurate diagnosis is impossible. The danger of spreading malignant disease by biopsy is probably not as great as has been feared by some writers. If an electric knife is not available the area from which the biopsy specimen is taken should be touched with formalin. If carcinoma of the corpus is feared diagnostic curettage may be performed. If large pieces of tissue can be curetted away easily and if the uterine wall feels soft under the instrument a malignant growth should be suspected. Frozen sections of curetted material have only a qualified value. If large pieces are obtained from a carcinomatous area satisfactory sections may be obtained. If only small bits are available unless all are striped and examined the cancerous area may be missed. Trauma may lessen the value of curetted material.

Treatment of carcinoma of the cervix may be by (1) radical excision—abdominal or vaginal, (2) irradiation—radium or deep x-ray or (3) heat—actual cautery or electrocoagulation.

At present in most clinics in this country radium treatment is the method of choice in carcinoma of the cervix. Unless the cancer is very early the surgical excision must be so radical that the primary operative mortality is high even in the hands of expert pelvic surgeons. The extended hysterectomy should not be attempted unless the parametrium is free and the rectum and bladder show no sign of extension. Vaginal invasion must be absent or so slight that it can be excised. The radical vaginal operation first described by Schmitt is advocated by some European writers; an excellent discussion of this procedure is given by Peham and Amreich. Ordinarily hysterectomy is not only useless but harmful.

greatest part of the effectiveness of radium is exerted at the first application. The practice in many clinics today is to irradiate both by radium and by x ray. Results seem to have been improved by this combination. The details of x ray therapy are for the radiologist to decide upon, but in general it may be said that deep therapy through a number of portals is best. Preliminary destruction of the visible portion of the tumor by electrocoagulation increases considerably the effectiveness of irradiation.

Carcinoma of the Corpus.—Carcinoma of the corpus is much less frequent than carcinoma of the cervix. It is usually an adenocarcinoma. The rate of growth is less than that of cervical cancers and metastases occur later and is not so extensive.

Diagnosis.—The uterus may be somewhat enlarged and relatively symmetrical. Irregular bleeding is the outstanding symptom. Bleeding in a woman well past the menopause after some years of amenorrhea with no other obvious cause of bleeding is highly suggestive if not pathognomonic. Curettage may be employed with histologic examination of the scrapings. It should be done gently as the carcinomatous organ is easily perforated and the danger of migration of malignant cells through the tubes with implantation in the peritoneum must be borne in mind.

Treatment.—In cases of carcinoma of the body of the uterus surgical treatment is preferred unless there is evidence of extension beyond the uterus. Excellent results are obtained by excision of the uterus including the cervix tubes and ovaries. The extended operation of Wertheim and Ries is not necessary. In cases in which extension beyond the limits of the uterus has occurred radium or x ray treatment may be employed instead of operation. Barnum reports 109 per cent of advanced cases of corpus carcinoma treated by irradiation alone. Healy suggests the value of irradiation in cases favorable for operation and with Cuthler reports 65 per cent of cures in a series of 23 cases.

CHORIONEPITHELIOMA

Chorionepithelioma is a highly malignant tumor. Since its appearance except in rare cases is preceded by the presence of fetal cells it therefore follows hydatid mole abor-

tion or possibly term pregnancy. Meyer has shown that the formation of a mole in an aborted embryo is very common. The possibility that a chorionepithelioma may develop after abortion is therefore evident. Chorionepithelioma may be preceded by hydatid mole but it is by no means true that every hydatid mole is followed by chorionepithelioma. It is found during the years of child bearing. In Tercher's series of 180 cases the average age was thirty three. The tumor usually appears soon after the termination of pregnancy. After three years its appearance is uncommon but longer periods are possible. Ries found chorionic villi in the uterus eighteen years after the last pregnancy.

Rapid metastasis is a marked characteristic and is often by way of the blood stream as a result of erosion of vessels in the uterus. The lungs are the most frequent site of secondary growths the vagina and vulva being next in frequency. Metastases may also be found in the liver urinary tract broad ligaments tubes and ovaries.

Symptoms.—The symptoms are often vague until the growth has developed beyond the possibility of removal. Pulmonary metastases causing hemoptysis and cachexia may be the first symptom. Bleeding following the expulsion of a hydatid mole is always suspicious. Diagnostic curettage should be performed at once followed immediately by surgical treatment if chorionepithelioma is found. The prognosis is bad death usually following within a year. There are however cases recorded of recovery after simple curettage.

Treatment.—A very hydatid mole should be completely evacuated. Schumann advocates abdominal hysterotomy in order that evacuation of the uterus may be performed under direct observation. If chorionepithelioma is found panhysterectomy with excision of the pelvic glands must be performed at once. Theoretically radium should be of great value because cells of fetal character are susceptible to it, but sufficient data are not yet available to make an accurate estimation of its value possible.

SARCOMA

Sarcoma is found infrequently. A number of reported series indicate that the number

of sarcomas is between 1 and 2 per cent of that of myomas. They are most frequent between the ages of forty and fifty. Vent reported a few cases in young women and children the frequency increasing from twenty five years upward. It is more frequently found in the corpus than in the cervix. The recurrent fibroids spoken of by some older writers were probably sarcomas. Both round cell and spindle cell sarcomas may be found. Mixed cell growths are also described.

Symptoms—Bleeding which is irregular and not associated with menstruation usually after the menopause is typical. Pain is frequent and may be caused by pressure on neighboring structures or by the rapid growth of the sarcoma. A sarcoma which develops in the cervix or lower uterine segment may produce rectal or vesical pain and a watery discharge may appear. In later cases in which sloughing has begun the discharge may be foul. Diagnostic curettage may be of value.

Treatment—If the condition is recognized early, when the growth is still confined to the uterus radical hysterectomy including the removal of the pelvic lymphatic glands is best. In later cases in which extension has occurred irradiation should be used preferably with radium which may be followed by x ray treatment.

TUMORS OF THE OVARY

Ovarian tumors may be solid or cystic about 90 per cent being cystic. Both cystic and solid tumors of the ovaries are usually benign. Carcinoma and sarcoma develop relatively infrequently.

Ovarian Cysts—The genesis of ovarian cysts is not known. They may be divided into the following groups:

1 *Simple follicular cysts* multiple usually bilateral and small consist of unruptured graafian follicles from which the ova have usually disappeared. Either the walls are lined by flattened cylindrical epithelium or there is no epithelial lining. The cysts contain serum either clear or turbid. Disturbances of the ovarian circulation appear to play a part in the etiology as in uterodisplacement with prolapse of the ovaries or venous stasis incident to uterine involution.

2 A *serous cyst* differs from a follicular cyst in possessing an epithelial lining unlike that of the follicle and displaying active proliferation (single layer of columnar epithelial cells). Unlike the cystadenoma there are no proliferating gland tubules in the cyst wall. The serous cyst is usually unilocular and pedunculated but may be intraligamentous. It is usually moderate in size but may attain enormous dimensions. In general it is unilateral and always benign (Figs 673 and 674).

3 A *cyst of the corpus luteum* is usually single and unilateral arising from a persistent corpus luteum. It may have orange-colored walls. Rarely does such a cyst exceed 6 cm in diameter. Hemorrhage into the cyst cavity is common. These cysts are benign. Cases of hydatidiform mole are sometimes associated with large bilateral cysts of the corpus luteum caused by an excess of anterior pituitary like hormone. An excessive amount of this hormone causes hyperlutinization and sometimes hyperfolliculization.

These cysts may regress with the expulsion of the mole but in many instances they persist although reduced in size. They should not be excised immediately but a reasonable period should be allowed to elapse after the extraction or expulsion of the mole in order to determine whether or not retrogression will take place.

4 *Endometrioid cysts* (chocolate cysts) en-

ometriosis) may be multiple and unilateral or bilateral. They arise from misplaced endometrial implants on the surface of the ovary and contain thick, tarry, altered blood. The walls are thick and many areas of characteristic endometrial glands may be seen

bryonal structures ectoderm in greatest development then mesoderm and lastly endoderm. Barzilai has defined *teratomas* as adult or embryonal forms. The mature teratoma is microscopically polymorphous and often cystic (dermoid cyst) and it usually

Fig. 3—Large serous cyst of the ovary (a thoracic case at the Kentucky Hospital for Women Physicians).

microscopically. Such cysts frequently rupture allowing the escape of some of the endometrial membrane and producing endometrial implants throughout the pelvis.

5 *Dermoid cysts* are usually unilateral and congenital. They are spherical masses

showing overgrowth of one tissue such as skin or thyroid tissue to the exclusion of all others. The adult teratoma is benign. The embryonal teratoma is generally a solid growth is made up of many tissues and is highly malignant.

Fig. 4—Large dermoid cyst.

ing from 15 to 20 cm. in diameter. The capsule is firm and white but turns yellowish on exposure to the air as a result of the coagulation of sebaceous material. The contents may be hair, bone, teeth, or sebaceous matter. All such cysts possess a small thickened area on the wall which contains all three em-

6 *Cystadenomas* (or endometriomas cysts) are characterized by the presence of rapidly proliferating gland tubules lined with a single layer of secreting epithelium. The cysts distend and rupture into one another and cavities of various sizes result. They may be unilateral or bilateral and they grow

to huge proportions cysts weighing from 175 to 190 pounds having been recorded. A cyst of this size causes stretching of the ovarian attachments into long pedicles. However as a rule they are much smaller 20 or 30 pounds being an average weight. The contents may be clear serum thick colloidal jelly grumous syrupy fluid old blood etc. The surface is always smooth and the contour globular. These cysts are usually benign. They sometimes rupture into the peritoneal cavity and the proliferating epithelium becomes implanted on remote structures producing pseudomyoma peritonei.

present masses of colloidal material intermingled with areas of fused papillae. They are adenocarcinomatous have a rapid growth and become ascitic early. Pain is a common symptom.

9 *Parovarian cysts* arise from the parovarium a remnant of the Wolffian body. They are unilocular and unilateral and grow between the leaves of the broad ligament. They are thin walled and flaccid and are recognized by the fact that in each case the fallopian tube is stretched over the surface of the cyst and enormously elongated and thinned out. The uterus is displaced as is the ureter making operation difficult. The

Fig. 63.—Multilocular papillary carcinoma of the ovary.

7 *Papillary cystadenomas* may attain a large size and are potentially malignant though in low degree. They are multilocular and thick walled and frequently rupture by erosion of papillae through the cyst wall producing secondary papillary growths throughout the peritoneal cavity. Microscopically the papillae of varying length and thickness are seen covered with columnar epithelium and sometimes massed as large condylomatous nodules.

8 *Cystic carcinomas of the ovary* (Fig. 65) may be primary (disputed) or the result of the degeneration of a cystadenoma. They are commonly bilateral and are difficult to distinguish from papillary cysts except by their greater solidity. They often

true wall of the cyst is covered by the broad ligament making a double wall. A pedicle is usually absent.

Solid Tumors of the Ovary—These are rare. They may be classified as follows:

1 *Fibromas* are usually of moderate size (12 to 15 cm. in diameter) and either solid or partially papillary. They tend to become malignant. The wall is smooth and the pedicle usually well developed. The tumor may be partially or completely calcified.

2 *Sarcoma of the ovary* is rare, commonly bilateral and round or spindle cell. It may be smooth or nodular; metastasis is slow.

* Curtis, Obstetrics and Gynecology, W. B. Saunders Co., Publishers.

3 *Granulosa cell tumors of the ovary* are rare semioestric tumors usually unilateral small to moderate in size and well encapsulated. Microscopically these growths resemble the granulosa cells of the normal ovary and have a tendency to form structures resembling graafian follicles and follicular cysts. They are probably benign although some appear to possess malignant characteristics. In elderly women granulosa cell tumors stimulate the endometrium and produce uterine bleeding. In children they characteristically give rise to precocious sexual development.

4 *Krukenberg tumors* are malignant growths usually secondary to gastrointestinal carcinoma. They are firm solid growths generally bilateral kidney shaped and sometimes lobulated.

5 *Brenner tumors* are now classed as benign. They vary greatly in size and resemble fibromas without a definite capsule.

6 *Dysgerminomas* arise from undifferentiated gonadal cells occasionally reach enormous size and are classed as malignant although the malignancy varies in different individuals.

7 *Arrhenoblastoma* is a masculinizing tumor originating in certain male-directed cells which persist in the ovary from early embryonal life.

Clinical Course and Symptomatology.—Benign ovarian tumors usually do not give rise to symptoms unless complications occur. The smaller cystic and solid growths are often unrecognized unless discovered by pelvic examination.

The larger tumors cause an increase in size of the abdomen and pressure symptoms later. Exceptions to this rule are endometrial cysts and the small follicular cysts. Occasionally disturbances of menstruation are present and a sense of weight is felt in the pelvis. Bilateral tumors usually give rise to amenorrhea.

Ovarian tumors grow slowly but steadily and eventually reach a large size. If not removed they may cause death from pressure on vital organs.

By pressure the larger tumors cause (a) irritability of the bladder (b) edema of the lower extremities (c) malnutrition with loss of flesh (d) menstrual irregularities (e) constipation and (f) ascites. There are no

specific symptoms. Endometrial cysts cause severe dysmenorrhea with menorrhagia and metrorrhagia and are sometimes extremely tender causing dyspareunia. Multiple follicular cysts cause great menstrual irregularity and frequently sterility and some times are the cause of a dull heavy aching in the iliac fossae.

Diagnosis.—The size of the tumor must be considered.

A small tumor present a vague history of some menstrual disorder or bladder irritability. Bimanual examination reveals a rounded fluctuating mass which is independent of the uterus. The mass may be anterior to the uterus in close approximation to the bladder. It may be fixed or movable. Usually the uterine corpus can be differentiated from the cyst but sometimes this is impossible. Tenderness is uncommon except in endometrial cysts. These are often fixed the outline usually being irregular and nodular. Large ovarian cysts may extend from symphysis to ensiform cartilage and may be smooth movable (sometimes very tender) and fluctuating with dullness over the tumor and tympany in the flanks. The abdomen is distinctly rounded (not flattened as in ascites) in profile when the patient is lying on the back. Pelvic examination is uncertain there is a sense of fullness in the vaginal fornices.

DIFFERENTIAL DIAGNOSIS.—A small ovarian cyst must be differentiated from (1) salpingitis and hydrosalpinx (2) ectopic pregnancy and (3) retroverted pregnant uterus.

1 *Salpingitis and hydrosalpinx* are characterized by (a) a history of an acute attack (b) marked tenderness (c) irregular outline (d) fixation in the pelvis (e) its frequent blending into the uterine outline (f) height of temperature leukocytosis and rapid sedimentation time.

2 *Ectopic pregnancy* is characterized by (a) a history of a missed or irregular period (b) slight uterine bleeding (c) pain sudden and afebrile (d) painful defecation (e) soft cervix slightly enlarged and softened uterus (f) positive Aschheim Zondek test and (g) an oval extremely tender mass in the vaginal fornix.

3 *Retroverted pregnant uterus* is characterized by (a) a history of pregnancy, (b)

positive Aschheim Zondek test (c) a mass in the median line and (d) objective signs of early pregnancy

B Large ovarian cyst must be differentiated from (1) ascites (2) pregnancy (3) fibroma uteri (4) obesity and (5) giant hydrosalpinx

1 Ascites is distinguished by (a) a history of cardiorenal disease cirrhosis of the liver tuberculous peritonitis or abdominal malignant disease (b) tympany anteriorly movable dullness in the flank (c) abdominal profile which is flat at the apex when the patient is supine and (d) absence of a palpable mass

2 Pregnancy is differentiated by means of (a) subjective and objective signs of pregnancy (b) fetal palpation (c) associated changes in the breasts (pigmentation) etc (d) x-ray plates and (e) an Aschheim Zondek test

3 Fibroma uteri is distinguished by (a) a hard dense usually nodular mass (b) a nodular (usually multinodular) dense tumor springing from the uterus and found on pelvic examination and (c) persistent menorrhagia and metrorrhagia

Complications of Ovarian Cysts (1) Rotation of cyst with torsion of pedicle 2 Inflammation suppuration of cyst with peritonitis 3 Rupture of cyst 4 Ureteral obstruction 5 Intestinal obstruction

1 *Rotation of the cyst caused by intestinal movement trauma etc* is frequent Torsion of the pedicle results and from one to seven turns may occur Torsion first produces interference with the venous return and a consequent intense engorgement of the cyst frequently followed by hemorrhage into its cavity Later there may be thrombosis of vessels and extravasation of blood into the abdominal cavity necrosis and gangrene of the cyst followed by general peritonitis The symptoms are sudden pain often following mild trauma or unusual exercise abdominal rigidity distention moderate shock pyrexia leukocytosis vomiting and dysuria Pelvic examination reveals a tense and extremely tender cystic mass

2 *Infection* will cause inflammation and suppuration The symptoms are pain rigidity of the rectum temperature indicative of sepsis rigors high leukocytosis and a rapid sedimentation time Later there are evidences

of chronic sepsis followed by rapid anemia and emaciation There is a possibility of rupture of a suppurating cyst into the bladder or rectum or rarely into the peritoneal cavity

3 *Rupture* may follow sharp abdominal traumatism or may result from overdistention of a thin walled cyst Usually no marked symptoms are present except a change in the character of the abdominal swelling malaise and marked diuresis usually followed by low grade peritonitis Sometimes recovery occurs if the cyst does not refill but more often there is continued leakage

4 *Ureteral obstruction* may be evidenced by oliguria pain in the lumbar fossae pyelitis and pyelonephritis with uremia

5 *Cysts* which become adherent to loops of intestine may cause obstruction followed by the usual signs

Treatment—Small ovarian cysts require no treatment but a yearly pelvic examination should be made in order to determine the rate of growth Large cysts demand surgical removal Tapping through the abdominal wall should never be done except to save life from pressure symptoms when a patient is unable to undergo operation Endometrial cysts may best be treated by excision If this is contraindicated irradiation to a menopausal degree may suffice Multiple small follicular cysts may be treated by resection of the diseased portion of the ovary leaving the hilus and as much of the parenchyma as is feasible Endometrial cysts were formerly treated by radical operations but as they commonly occur in young women in whom the preservation of ovarian function is important a more conservative attitude prevails at present Papillary cysts should be removed if possible intact Irradiation should follow because of potential malignancy Dermoid cysts should be removed intact as soon as discovered

Operative Technique—*Resection of the Ovary*—The usual abdominal preparation should be carried out and a midline incision made The cystic ovary is seized with Allis clamps and a wedge-shaped piece is excised care being taken to include all the cystic area The cut surfaces are carefully approximated by a running suture of 0 catgut with

fine mattress sutures occluding the blood vessels (Figs 676 and 677) Uterine suspension prevents prolapse of the ovary into the cul de sac with the formation of adhesions

Papillary Cyst—A large incision is made and every effort exerted to prevent rupture of the cyst and escape of the contents into the abdominal cavity. If the cyst should rupture a careful peritoneal toilet is imperative

Fig 66—Resection of the cystic portion of the ovary. All cyst tissue must be removed

Large Cysts—Local anesthesia is peculiarly applicable in such cases. A small midline incision is made and the surface of the cyst grasped with Allis forceps; the serosa nicked and a trocar introduced. Gruze packing is used to prevent leakage of fluid. When the tension has been slightly reduced the trocar is fastened in place by purse string

sutures and postoperative irradiation should be used to prevent the growth of malignant cells which may have entered the peritoneal cavity.

A dermoid cyst should be removed intact if possible. A cyst of the broad ligament may be extremely difficult to remove. Being thin-walled it collapses easily, leaving a

Fig 67—Repair of the wedge-shaped cavity in the ovary; atraumatic interrupted sutures of fine catgut

sutures or several clamps and the cyst emptied. Then the trocar is withdrawn, the opening is closed by clamps and the fluid cyst wall is gently pulled through the incision, adhesions being cut as they are met. The pedicle is then ligated with chain gutures and cut. The pedicle stump is peritonized if possible and the wound closed.

large space in the vascular portion of the broad ligament. Great care must be taken not to injure the probably displaced ureter or to include it in the suture when the gap in the broad ligament is being closed. This type of cyst in some cases may be easily removed by enucleation, the broad ligament being opened at its lateral pelvic attach-

ment and the cyst stripped from between its leaves

Treatment of Complications of Ovarian Cyst—Torsion of the pedicle demands immediate operation. Ligation of the pedicle and removal of the cyst must be followed by drainage if peritonitis has commenced. Blood transfusion and other supportive measures are frequently necessary to combat shock and infection.

Suppurating cysts should be removed entire if possible. If leakage occurs a careful toilet and drainage are indicated.

Occasionally it is best simply to evacuate the purulent contents of the cyst and suture the cut edge of its wall to the abdominal wall (marsupialization). When infection subsides the cyst may be removed and the wound closed. In cases of follicular serous dermoid and endometrial cysts the opposite ovary if apparently healthy may be allowed to remain. In papillary and pseudo-mucinous cysts both ovaries should be removed usually with hysterectomy. If the ovarian cyst is malignant wide panhysterectomy is indicated.

Treatment—Fibromas may be excised by simple oophorectomy. A sarcoma or carcinoma demands panhysterectomy with removal of both ovaries followed by intensive postoperative irradiation.

As carcinoma of the ovary is often secondary a careful roentgenographic study of the intestinal tract and other investigations should be carried out prior to operation. The discovery of a primary tumor remote from the pelvis renders useless an excision of the ovarian growth. Complete hysterectomy is the procedure of choice in the absence of metastasis even though but one ovary is involved. If the tumors are inoperable no attempt at removal should be made. Treatment should consist of intensive irradiation.

RETRODISPLACEMENTS AND PROLAPSE OF THE UTERUS ETC

RETRODISPLACEMENTS OF THE UTERUS

The position normally assumed by the uterus is that of anteversion but this position is subject to physiologic changes. Thus the bladder causes the uterine body to drop backward or rise as it becomes filled or emptied. The distended rectum likewise may influence the uterine position. The cervix being more firmly fixed allows less mobility. With the bladder empty the long axis of the uterus is at right angles to the axis of the vagina (Fig. 678 a).

Definition—Retrodisplacement of the uterus is a term applied to (a) *retroversion* which is a backward rotation of the uterine body toward the promontory of the sacrum or below that point (Fig. 678 d), (b) *retroflexion* which is a bending backward of the uterine body on itself (Fig. 678 c), (c) *retrocession* which is a dropping backward of the entire uterus (Fig. 678 f).

Etiology—(a) *Congenital* retrodisplacements commonly occur in young nulliparous women and (b) *acquired* retrodisplacements occur as a result of (1) childbirth injuries, (2) uterine subinvolution, (3) neoplasms, (4) adnexal inflammation and (5) endometriosis.

Pathology—(1) In *congenital* retrodisplacements such as retroflexion and ante-flexion faulty development of the uterine ligaments and fascial supports is usually evident the uterus being hypoplastic in

type. The anterior vaginal wall is commonly shortened.

(B) *Acquired* retrodisplacements result from relaxation of the uterine supports. As a result of retrodisplacements the intestines rest in the vesicouterine pouch, the adnexa drop into the cul-de-sac and the bladder is drawn backward. The backward rotation of the uterine body causes torsion of the blood vessels of the broad ligaments, resulting in passive congestion of the uterus and the development of varicosities in the broad ligaments. The fallopian tubes and ovaries become passively congested and formation

a feeling of weight in the pelvis with a bearing down sensation. (3) menstrual symptoms such as menorrhagia or dysmenorrhoea. (4) leucorrhoea resulting from hypersecretion of the cervix. (5) dyspareunia occurring if the ovaries are prolapsed in the cul-de-sac. (6) frequency of urination if the trigone of the bladder is pressed on, (7) constipation from pressure on the lower bowel and (8) sterility or repeated abortions. The symptoms of retrodisplacement due to an associated pathologic condition are chiefly those of the diseased condition causing it.

Fig. 68.—a Normal; b retroversion on first degree; c retroversion on second degree; d retroversion on third degree; e retroflexion; f anteversion with retroversion.

of follicular cysts of the ovary may result. Passive congestion of the cervix causes hypertrophy of the musculature and cervical glands. Displacements due to or associated with inflammatory lesions are frequently fixed posteriorly by adhesions.

Symptomatology.—(A) *Congenital* retrodisplacements seldom cause symptoms, although dysmenorrhoea and sterility are often associated and are probably due to faulty development. (B) *Acquired* retrodisplacements may also cause no symptoms. If any are present the most frequent complaints are (1) lumbosacral backache, (2)

Diagnosis.—The diagnosis of retrodisplacement is made by bimanual examination. Rectovaginal examination is of additional value in making a diagnosis, especially in obese women. Myomas of the uterine wall, ovarian cysts and inflammatory exudates behind the uterus may lead to confusion in the diagnosis. In questionable cases a uterine sound may be introduced to determine the position of the fundus, but should be used only under strict aseptic precautions and never when pregnancy is suspected.

Prognosis.—While congenital retrodis-

placements seldom cause symptoms endometriosis of the pelvis may occur because of retrograde menstruation. Acquired retroplacements predispose to prolapse of the uterus.

Treatment.—Symptom free patients require no treatment. Retrodisplacements occurring after childbirth are often corrected by means of the knee chest position. Others require replacement and support by a suitable pessary until involution is complete. Retrodisplacements with associated vesical discomfort and frequency of urination require careful study of the urine as cystitis may be the cause. Uterine replacement and retention in a normal position with a pessary is a reliable test to determine the amount of relief obtained. If symptoms disappear surgical treatment is usually advisable provided there is no contraindication.

Operative measures for the correction of retroversion are most satisfactorily performed intra-abdominally. They should be devised so as to use the natural supports of the uterus to insure mobility to allow pregnancy to occur to be easy of execution and to be lasting in their results (Gilliam). Cniffe's anterior plication and the Bldt-Webster posterior plication of the round ligaments are satisfactory procedures. Gilliam's operation of pulling the round ligament through a stab wound made through the rectus muscle and suturing it to the anterior sheath is also a satisfactory procedure. In most instances the uterosacral ligaments should be shortened in addition to the round ligament plication.

PROLAPSE OF THE UTERUS URETHROCELE, CYSTOCELE, ENTEROCELE AND RECTOCELE

These lesions are all true hernias of the pelvic viscera into or through the vaginal canal. Since they have a common cause and are frequently associated they are best studied collectively.

Synonyms and Definitions.—*Prolapse of the uterus* (*procentia descendens uteri* or falling of the womb) is a permanent descent of the uterus from its normal position (Fig. 679). *Urethrocele* is a prolapse of the urethra (Fig. 680). *Cystocele* is a hernia of the base of the bladder (Fig. 680). *Enterocoele* is a hernia of the cul-de-sac with

its intestinal contents (Fig. 679). *Rectocele* is a hernia of the rectum (Fig. 681).

General Discussion.—The bony pelvis is closed by a diaphragm consisting of the levator ani and coccygeus muscles with a strong layer of fascia above and below. This diaphragm is pierced anteriorly by the vaginal canal and urethra. Reinforcing the diaphragm below is the triangular ligament which extends from one pubic ramus to the other. The uterus, bladder and rectum are retained in normal position by strong elastic bands of connective tissue and muscle. The pelvic diaphragm does not support the uterus but counteracts the strain of intra-abdominal pressure. The round and uterosacral ligaments act mainly in tilting the uterus forward.

Etiology.—Prolapse of the uterus and its associated lesions are usually due to childbirth injury and occur most commonly in women who have had a number of children or difficult labors. In nulliparous women prolapse is usually the result of a congenital defect of the tissues. Coughing or straining predisposes to these lesions. Changes which occur in the tissues in advanced age also favor prolapse.

Pathology.—Labor and childbirth subject the muscular, fascial and connective tissue structures of the pelvis to various types of injuries. Thus *urethrocele* results from injury to the supporting structures which normally surround the urethra. *Cystocele* occurs because of injury to the pubocervical fascia causing it to become thinned and to spread laterally. It is most commonly associated with prolapse of the uterus for the position of the bladder depends to a great extent on the position of the cervix. *Cystocele* varies from slight to complete herniation of the entire bladder. Retention of urine occurs if the hernial sac is below the level of the urethra. *Prolapse of the uterus* results from relaxation of the uterine supports particularly of the broad ligaments. The prolapse is *incomplete* if it remains within the vagina or *complete* if it protrudes beyond the introitus. Prolapse is usually preceded by retroversion of the uterus then being forced downward by the intra-abdominal pressure. The vaginal canal is commonly dilated and the perineum relaxed. Elongation of the cervix is often an asso-

erated condition. Ulceration of the mucous membrane of the protruding vagina and cervical erosions are frequent. The cul-de-sac may descend with the cervix dissecting its way downward between the rectum and the posterior vaginal wall forming an *enterocele*. Hernia of the rectum having its origin above the perineal body is often seen. This is known as a *high rectocele* and is due to separation of the perirectal fascia. *Low rectocele* occurs when the perineal body is injured so as to cause the rectum to bulge into the vaginal opening (Fig. 681).

Symptomatology.—Most patients com-

of difficult labors with symptoms which are usually characteristic. Examination of the

Fig. 680—*a* Enterocele. *b* cystocele examined with incomplete prolapse. (A sound has been inserted in the bladder.)

patient in the erect posture is of value. In cystocele the presence of residual urine is diagnostic. Cystoscopy aids in differential

Fig. 679—Prolapse of the uterus with (*a*) cystocele and (*b*) enterocele.

plaint of a bearing down pain, a feeling of weight in the pelvis and lumbosacral back ache. Others complain only of the protruding mass, particularly when standing on their feet. If urethrocele is associated there is often incontinence of urine. In cystocele residual urine causes irritation of the bladder resulting in urinary frequency. Inability to start the flow of urine without first replacing the protruding part is the complaint of many. Difficulty in defecation is common when rectocele is present. Leukorrhea occurs when erosion of the cervix or vaginal walls exists.

Diagnosis.—The diagnosis of prolapse of the uterus and its associated pathology is made without difficulty. There is a history

Fig. 681—*a* Rectocele with finger inserted in rectum to demonstrate the hernial sac.

ing such conditions as a stone or other lesions of the bladder.

Treatment—(A) *Preventive* measures include (1) the proper conduct of labor prohibiting expulsive force before cervical dilation (2) episiotomy to prevent extensive perineal injuries (3) immediate perineal repair following labor (4) adequate puerperal rest and (5) examination six weeks after delivery and if retroversion has occurred replacement and support by means of a pessary until involution is complete (B) *Palliative* measures rest in bed and replacement of the uterus until congestion has subsided and ulcers and erosions have healed support when possible by properly fitted pessaries (C) *Curative* measures Surgical treatment is employed (1) in child bearing women with cystocele and prolapse of the uterus the bladder is advanced then the pubocervical fascia is reunited and the anterior vaginal wall is

reconstructed (Fig 682 b) In complete prolapse vaginal hysterectomy (Mayo) is employed when the uterus is atrophic In this operation the remaining broad ligaments are united in the midline forming a hammock on which the bladder rests This is followed by perineorrhaphy (Fig 682 c) Incontinence of urine is best controlled by uniting the relaxed sphincter muscle of the bladder in the midline with mattress sutures (Kelly)

Other surgical procedures recommended for prolapse are anterior colporrhaphy with amputation of the cervix and reconstruction according to the technic of the Manchester operation The perineum must also be reconstructed

For elderly women with extreme prolapse in whom marital relationship is no longer a factor the La Forte procedure gives excellent

Fig 682—Lateral view showing principles of operative procedure advised in cystocele and prolapse a Advancement of bladder b interposition operation c vaginal hysterectomy

sutured to the cervix from the internal os down thereby closing the hernial opening (Fig 682 a) The cervix may then be amputated and shortening of the cardinal ligaments employed to raise the prolapsed uterus This is followed by perineal repair In incomplete prolapse this may be all that is necessary If after these procedures the fundus does not remain forward intra-abdominal shortening of the round and utero-ovarian ligaments will place the uterus in normal physiologic position (2) In non-child bearing women surgical correction depends on the degree of prolapse and the size of the fundus In incomplete prolapse the interposition operation (Watkins) is indicated when the uterus has not atrophied and cystocele is the outstanding finding It consists of interposing the fundus of the uterus between the bladder and the anterior vaginal wall The perineum should be

results This consists of triangular denudation of the anterior and posterior vaginal walls from the cervix downward to the vaginal orifice and uniting of the same from above downward thus retaining the prolapsed organs within the vagina

PERINEAL LACERATIONS AND RELAXATIONS

The important structures making up the perineal body are the two pubococcygeus columns of the levator ani muscle running from the pubis above along either side of the vagina and inserting in the sides of the rectum and the anococcygeal ligament Reinforcing these muscles below is the triangular ligament a fascial floor extending from one pubic ramus to the other The function of the perineal body is to guard the vaginal opening

Injuries of the perineum occur most frequently as a result of childbirth and are due to marked stretching or lacerations. Such lacerations may be superficial or deep in complete when involving the perineal body.

Operations devised to repair perineal lacerations and relaxations require submucous exposure of the structures which compose this body and reconstruction. A modified Hegar's operation in which the bellies of

DISTURBANCES OF MENSTRUATION

UTERINE HEMORRHAGE

Menorrhagia—In most cases menorrhagia is caused by lesions of the organs concerned with menstruation viz the uterus the ovaries and the controlling glands of internal secretion. The most important glands of internal secretion that modify the menstrual function in this way are the ovaries, pituitary and thyroid. This type of menorrhagia is called functional menorrhagia and thyroid extract is often effective in its cure. Some of the newer gonadotropins offer promise in control of the bleeding. Anovulatory bleeding may take the form of menorrhagia or metrorrhagia.

Local lesions which cause menorrhagia are fibromyomas pelvic and vaginal inflammations hyperplasia of the endometrium polyp carcinoma of the corpus uteri endometriosis sarcoma and ovarian neoplasms. These lesions may also produce metrorrhagia but usually only when they are complicated with degenerative changes torsion or infection.

Metrorrhagia—Metrorrhagia is irregular because it is not a result of rhythmic changes of the menstrual cycle. Blood loss of this type is usually the result of actual damage to the vascular system of the pelvis by trauma necrosis or infection. Examples of this form of bleeding are contact bleeding in carcinoma of the cervix irregular spotting from a necrotic myoma a disturbed intrauterine or ectopic pregnancy and bleeding associated with pelvic infections.

Sudden profuse hemorrhage occurring in a patient who has been menstruating regularly is almost pathognomonic of a disturbed pregnancy.

Metrorrhagia may be caused by carcinoma anywhere in the genital tract but especially in the cervix cervical lesions ectopic pregnancy and ulcerations of the vagina. Metrorrhagia is abnormal and demands attention. Profuse or irregular bleeding calls for diagnostic curettage and biopsy.

AMENORRHEA

Amenorrhea means absence or cessation of menstruation. It may be physiologic or pathologic. Physiologic amenorrhea occurs before puberty during pregnancy or lactation and following the menopause. Uterine bleeding during these periods is abnormal. Amenorrhea during lactation lasts normally for from six weeks to four months. If it lasts longer another pregnancy may be suspected.

Menstruation usually begins between the eleventh and sixteenth years. Irregularity of the interval and duration of the flow are quite common and should not cause concern unless too pronounced. Delayed puberty may be due to hypoplasia of the genital organs. The amenorrhea which occurs in atresia of the genital tract is not a true amenorrhea but a retention of secretion and treatment of the stenosis will establish the normal rhythm. Replacement therapy with those hormones which stimulate the müllerian tract in certain cases is known to have the power to overcome some of the minor degrees of hypoplasia.

After the menstrual habit is once established any period of amenorrhea indicates pregnancy. Error will be avoided if this is assumed until disproved. The recently developed tests for pregnancy are very accurate and should be used more frequently.

The normal menopause is characterized by complete and permanent amenorrhea. Later bleeding should be regarded with suspicion.

Castration either surgical or by irradiation produces amenorrhea. Diabetes psychoses tuberculosis syphilis and morphinism may cause amenorrhea. Functional amenorrhea may be produced by a fear of pregnancy or by any marked emotional disturbance. A marked change in climate also may cause amenorrhea.

RELATIONSHIP OF THE GLANDS OF INTERNAL SECRETION TO GYNECOLOGY

The glands of internal secretion are important in the physiology of the female organism. Knowledge in this field increases rapidly and necessitates the frequent revision of ideas.

Among the most important effects are the pituitary, ovarian and thyroid. Cyclic changes are produced which are necessary for reproduction.

Investigation indicates that the pituitary gland is the initiator of this cyclic process. Hypophyseal hormones largely from the anterior

Fig. 686—Diagram illustrating the menstrual cycle for a primipara.

Fig. 68—Schematic drawing to illustrate the interrelationships between the various glands taking part in the cycle of changes of the pelvic organs. The arrows indicate action in both directions. When the excretory level is reached a rest mutation of the motor (pituitary) occurs and a new cycle is initiated. The resultant phases in the uterine mucosa are shown in figure 686. (After Moore.)

All the glands of internal secretion by their reciprocal action play a role in the physiology of the female reproductive system. Secretions from any one of the glands may stimulate or depress the other members of the endocrine system. The gland products

of the anterior lobe stimulate the gonads. Ovulation is an excretory (gametogenic) and a secretory (endocrine) function. During the ripening of the egg the growing follicle produces

* Vazir and Collier. Clinical Endocrinology of the Female. Charles C. Thomas Publisher.

duces a hormone called estrin (folliculin female sex hormone). This hormone acts on the uterus and vagina producing the changes found in the first half of the menstrual cycle. The activity in the endometrium is intensified and completed by another ovarian hormone, progesterin. Progesterin is produced in the corpus luteum. Its action is necessary for the preparation of the field for the implantation and early growth of the fertilized ovum.

The gradual increase in concentration of one or both of these hormones in the blood depresses the gonadal stimulating activity of the pituitary. Further ovulation does not occur until the stimulation threshold is again reached by excretion of sufficient quantities of hormone. At this time the pituitary again comes into the secretory phase and the cycle (Fig. 687) is repeated.

The secretion of the posterior lobe of the pituitary is called pituitrin. It has been divided into two active principles, oxytocin and vasopressin. Oxytocin produces contraction of the uterine muscle. Vasopressin possesses the three remaining functions of the posterior lobe: (a) an antidiuretic effect, (b) stimulation of gastrointestinal peristalsis and (c) the pressor-depressor effect.

DYSMENORRHEA

Dysmenorrhea may be classified as follows: (1) essential or primary dysmenorrhea and (2) acquired dysmenorrhea. Women who have suffered since the beginning of menstrual life constitute the essential or primary group, while those who later acquire pain comprise the second group. The acquired type may be engrafted on the essential form, but a carefully taken history will help to distinguish them.

Cause.—The cause of pain in the primary dysmenorrheas and in a few of the acquired types is not well understood. Recent investigation indicates that it is due to a disturbed physiology and consequent abnormal motility of the müllerian tract. Hormonal balance is essential to the normal function of the pelvic organs. Defects in development ranging from complete stenosis of the genital tract to mild degrees of infantilism may produce an essential dysmenorrhea. Congenital malpositions of the uterus may be associated with dysmenorrhea. Hypoplasia with lack

of adjustment to the changes in size and tension during the menstrual cycle offers a more rational explanation of pain than malposition, especially as surgical reposition often fails to give relief. Interference with the outflow of menstrual blood through the cervix, especially in a patient who has a long conical cervix with a very small canal, must still be considered, since about half of the patients with primary dysmenorrhea are relieved by dilation. More recent investigations may indicate that the relief of pain may be due largely to the mechanical effects of the surgical treatment which change the endocrine balance.

Common causes of acquired dysmenorrhea are pelvic inflammations, fibromyomas, especially of the intrauterine type, endometriosis, hyperplasia of the endometrium, polyps, acquired malpositions of the uterus, cervical erosions, ovarian neoplasms and psychic or debilitating diseases.

Treatment.—The treatment of essential dysmenorrhea is often unsatisfactory since the cause is not known. Analgesics or antispasmodics such as atropine may suffice until a change of hormonal status is caused by marriage or pregnancy. Recent reports indicate that replacement hormonal therapy may eventually solve many of these problems.

Dilation of the cervix will relieve about one half of these patients. Some of the remainder obtain partial relief. Mutilating operations on the cervix such as wedge-shaped excisions, dissection and tearing with mechanical dilators are contraindicated. Operations for the correction of retrodisplacement are seldom indicated and should be employed only after other treatment has failed.

Since any disease which increases pelvic congestion or produces an abnormal growth in the pelvis may cause acquired dysmenorrhea, the treatment varies with the underlying pathologic condition. Conservatism is essential because the patients are young women. Medical management will cure most of the inflammations. Myomectomy may save a fibromatous uterus. Conservative surgery rather than surgical or radical castration is advised for endometriosis. If a properly fitted pessary gives relief, then the patient may be relieved by a retrodisplacement operation.

Membranous Dysmenorrhea—Membranous dysmenorrhea is so termed because the endometrium is shed *en bloc* or as large shreds at each period. Expulsion of these casts of the uterus produces pain similar to that of abortion. The explanation for this desquamation is not clear but it probably is an abnormal reaction of the endometrium to its hormonal stimuli. However in some cases previous postabortive uterine infection seems to play an important role. Treatment is yet to be determined. Premenstrual curettage followed by the application of tincture of iodine to the uterine cavity. These patients are usually sterile and vaginal hysterectomy may be performed if the condition is severe.

MENOPAUSE

The climacteric or menopause denotes the cessation of menstruation. Most women reach the menopause between forty and fifty years of age. A smaller number continue to menstruate after fifty. Cessation before forty years of age is due usually to derangement of other glands of internal secretion rather than to a running down of the glandular mechanism.

The onset may be abrupt but more often is gradual and characterized by a decrease of menstrual flow and a lengthening of the interval between periods. Often nervous instability appears causing the so called hot and cold flashes, attacks of vertigo, ringing in the ears, headache and palpitation. Irregular bleeding, however slight, after the menopause raises the question of a malignant growth.

Changes in the pelvis are more constant and marked. Cessation of cyclic stimulation causes progressive atrophy, the ovaries become sclerotic and shrunken, the uterus and its supporting structures lose their tone and become smaller and a loss of support causes the uterus to assume a backward position and to sag downward. The fallopian tubes become straight and attenuated, the cervix shrinks until it may be almost flush with the vaginal vault, the latter becomes more conical and later adhesions of the cervix or vaginal walls may appear. The vagina loses its former elasticity and becomes smooth and rigid. This process of atrophy extends also to the external genitals.

Treatment—Treatment of the meno-

pause may be general or local. General treatment is directed toward stabilizing the disturbed nervous system. A strict schedule including adequate fresh air and sunshine, high vitamin intake, the use of sedatives such as bromides or the barbiturates and the avoidance of fatigue is beneficial. Substitution therapy with a potent product of the female sex hormone in most cases will produce satisfactory results. Local treatment includes examination at intervals of six months. Short intensive courses of estrogenic therapy given hypodermically may afford lasting relief. If symptoms recur estrogens by mouth in interrupted series are often sufficient. Minimal dosages should be adhered to as over dosage frequently causes postmenopausal uterine bleeding. Investigation of irregular bleeding or unusual secretion, maintenance of normal drainage from the cervix and vaginal canal and correction of areas of chronic inflammation such as erosions of the cervix are essential.

STERILITY

Sterility occurs in from 8 to 15 per cent of marriages and therefore is an important problem. Diagnosis may require the united efforts of the gynecologist, urologist and endocrinologist.

Primary sterility denotes failure to conceive under normal conditions in from two to five years. Failure of conception in a patient who has previously borne a child is called *secondary sterility*.

Sterility may be further divided into two groups. Absolute sterility means that impregnation is impossible; often a developmental defect of the pelvic organs is present. A larger group forms the class of relative sterilities. These embrace those conditions which make pregnancy not impossible but difficult. In such cases the best results are obtained.

In studying sterility it must be remembered that the fault in one third or one half of these cases may be with the husband and he should be examined before treatment of the wife is begun. Conditions which affect male reproductive power are inflammations such as gonorrhea and tuberculosis, metabolic diseases, psychic disturbances, developmental defects, drug addiction and chronic alcoholism. Important causes of female ster-

ility are pelvic inflammations especially of the cervix and fallopian tubes gonorrhea postabortive infections acute appendicitis and tuberculosis Metabolic diseases and dysfunction of the thyroid pituitary and ovaries are also frequent New growths such as fibromiomas ovarian tumors and endometriosis may interfere with conception

Diagnosis—Diagnosis of the cause of sterility is usually a process of elimination which should follow an accurate plan The first step is a history of both husband and wife noting duration of sterility use of contraceptives sexual compatibility general health and previous infections or operations This is followed by a physical examination of both partners Attention should be paid to stigmas of hypoplasia infection glandular dysfunction and psychic disturbances It is usually necessary to include complete microscopic study of the semen insufflation or occasionally visualization of the tubes and the usual blood tests including the Wassermann test and a differential count

Treatment—The indiscriminate use of tubal insufflation and particularly the injection of an opaque medium for purposes of visualization are deprecated Relative sterility may be made absolute by the unintelligent use of these procedures They should never be performed in the presence of infection or bleeding The ideal time is about one week after the menstrual period and then should be carried out under aseptic conditions

Improvement of the general health a liberal high vitamin diet a sensible sex regime or hormonal therapy such as thyroid medication will often suffice Cauterization affords a simple method of treating infections of the cervix Careful diagnosis and treatment of the vaginal infections especially those due to trichomonas vaginalis and yeast will restore the important normal vaginal acidity Infections in the pelvis proper do not lend themselves to such active treatment but many of them will improve functionally under conservative treatment Artificial insemination is not recommended because of the risk of infection

Indications for the surgical relief of sterility should be very clear Dilatation of the cervix often proves beneficial and is relatively safe Amputation and repair (trachel

orrhaphy) require an expert technique otherwise a relative sterility may become absolute Early habitual abortion may follow A retrodisplacement operation is not indicated unless the necessity for it has been shown by the use of a pessary Myomectomy should be performed only after other methods have failed and when the tumor does not encroach on the uterine cavity Conservation of as much normal ovarian tissue as possible is essential

The results of autotransplantation or heterotransplantation have not been sufficiently successful to warrant their general use Operative restoration of tubal patency becomes more promising in view of recent work These operations should be undertaken only after the patient has been told of the infrequency of cure and only by someone who is entirely familiar with the detailed technique

ECTOPIC PREGNANCY

Ectopic or extrauterine pregnancy exists when the implantation of the fertilized ovum occurs anywhere outside the uterine cavity. Most ectopic gestations are found in the fallopian tube chiefly in the ampulla some times in the isthmus rarely in the interstitial tube and only very seldom in the ovary and most infrequently in the abdominal cavity (Figs 688 and 689). It may occur as often as once in 300 or 400 pregnancies.

Etiology—The cause may be anything which retards the progress of the fertilized ovum toward the uterus thus permitting it to reach the trophoblastic stage of development when it has the power of implantation wherever it may be. The cause may be in the ovum or the tubes.

Causes Due to the Ovum—The ovum may be too large to traverse the tube because of the adhering membrana granulosa or rapid cell division or growth during the interval of transmigration.

Causes in the Tube—Formerly inflammation was considered the chief cause of tubal nidation but now it is considered more or less accidental and really depends more upon the location of the ovum when the trophoblast becomes capable of producing implantation (W Blair Bell). Although the etiologic role of pelvic infection has been overestimated salpingitis is a factor because of destruction of cilia or adhesions of tubal folds forming pockets and strictures. Likewise perisalpingitis may cause external adhesions kinks narrowing of the tube lumen and interference with peristalsis. Tubal diverticula accessory ostia ending in blind sacs tortuous infantile tubes double narrow lumina or tumors which distort or constrict the tube may favor tubal nidation.

Pathology—The ovum erodes its way into its ectopic location exactly as it does into the endometrium but the results are inevitably pathologic because the fallopian

tube or any other site is completely unsuited anatomically and histologically for the reception or development of the conceptus.

Decidua—There is no true decidua although there is usually a 'decidual reaction' in the form of decidual patches islands and isolated cells.

The Basalis—Because there is no protecting true decidua at the site of nidation the ovum almost immediately erodes its way directly into the muscularis thus weakening the tube wall literally riddling and weakening the muscular layers and opening relatively large vessels. The resulting hemorrhage overfills the intervillous spaces frequently crushing the villi into tangled masses. Often the capsule is so distended that it ruptures.

The Capsularis—At first the ovum is entirely intramuscular. As it grows it bulges

Fig 688—Tubal pregnancy ampullar implantation. The tube wall is unruptured. Beginning internal rupture (tubal abortion) started by small amount of blood in the abdomen.

into the lumen of the tube pushing the surrounding muscle wall and mucous membrane before it and producing a false capsularis. This pseudocapsularis soon comes in contact with the opposite tube wall which then bulges away from the site of implantation (Figs 688 and 689). There is no true decidua in this pseudocapsularis although decidual cells and islands of decidua are more often found than in the pseudobasalis. Villi at

* Nelson's Loose-Leaf Surgery, Thomas Nelson and Sons, Publishers

tracking the vessels of the tube are seen in figure 690

Tubal Rupture and Abortion—Rupture may occur externally through the tube wall into the abdominal cavity or internally through the pseudocapsularis into the tube lumen commonly called tubal abortion. The writer has been able to demonstrate the bursting of the inner capsule (Fig. 690) in every specimen of so called tubal abortion that he has examined microscopically in serial sections. Therefore he prefers the term internal rupture to tubal abortion.

When not ruptured through the tubal wall the pregnancy is often erroneously said to be unruptured even when blood is found in the abdomen. If there is blood in the peritoneal cavity a pregnant tube is always ruptured either internally or externally.

An ovum protruding through the ostium abdominale of the tube is according to this writer's observation not usually due to expulsion by muscular action of the tube but more often due to implantation of the ovum so near to the fimbriated extremity that it grows in the direction of least resistance—out through the end of the tube.

Changes in the Uterus—The uterus is enlarged and softened and decidua is formed in the uterine cavity in every case of ectopic pregnancy. The decidua persists until the death of the ovum then it degenerates bleeds (the source of the characteristic vaginal bleeding) and is cast off in debris patches of decidua or a cast of the uterine cavity.

As soon as the ovum dies the endometrium begins to regenerate and resumes its cyclic changes often even before the pregnancy is terminated. As long as living villi persist genital bleeding continues.

Ectopic pregnancy recurs in the remaining tube in from 10 to 15 per cent of cases. Twin ectopic pregnancy exists when there are two embryos in one tube one in each tube or one in a tube and another in the uterus.

Diagnosis—While amenorrhea is presumptive evidence of normal pregnancy delayed protracted or otherwise abnormal menses are suggestive of ectopic pregnancy especially when accompanied by anomalous vaginal bleeding pain fever leukocytosis and a mass to one side or behind the uterus.

The symptoms vary with the time the patient is first seen before during or after rupture.

Diagnosis before Rupture—Vaginal bleeding and pain are rare before rupture although there may be mild cramps but usually only discomfort soreness or indefinite distress. At this time there is no abdominal bleeding therefore no consequent fever or leukocytosis is noted. Before rupture because the ovum is usually alive the Aschheim Zondek test (or one of its modifications) is valuable.

The usual signs of pregnancy are not marked and subjective and objective symptoms are so elusive that definite diagnosis is difficult. The intradermal injection of colostrium (the Fall test) may prove to be quite as valuable as the rabbit test.

Diagnosis during Rupture—This is the most important period in the clinical course because the diagnosis missed before rupture may now be corrected and the impending tragedy of frank rupture may be avoided by a timely operation.

Fortunately the signs and symptoms are more definite. Pain the most constant subjective symptom is sharp lancinating and definitely on one side of the pelvis. Fluctuations of pain followed by temporary or complete relief are particularly significant.

The cervix is exceedingly sensitive to movement of the examining finger. Vaginal bleeding may be constant or intermittent dribbling or spotting rarely is it profuse and clotted usually it is brownish red. Abdominal bleeding recurs or increases with each paroxysm of pain and is always accompanied by fever and leukocytosis.

Ectopic pregnancy must always be kept in mind when dealing with an acute abdomen.

When examination is made under anesthesia the utmost gentleness is imperative otherwise the pregnant tube may be ruptured.

Diagnosis after Rupture—If diagnosis is delayed until after rupture a serious error has been made. One should not wait the agonizing pain on one side accompanied by violent internal hemorrhage followed by nausea vomiting rapid feeble pulse cold sweating pallid skin shallow breathing air hunger restlessness and extreme anxiety.

Over the side of the ruptured tube there is excessive tenderness and rigidity, sometimes the whole abdomen is distended and tender, a bluish black discoloration about the navel (Cullen's sign) indicating extensive abdominal hemorrhage may be present.

Differential Diagnosis—The principal conditions to be differentiated are uterine abortion, pelvic infection, appendicitis or any acute abdomen.

Abortion—Abortion shows profuse bleeding with clots, the pain is intermittent, cramplike and progressively increasing. Parts of the embryo or villi in the vaginal discharge render the diagnosis of abortion certain. Ectopic pregnancy is more likely when

maternal disease. If puncture of the vaginal vault shows blood, an ectopic pregnancy is present.

Other Conditions—Other acute abdominal conditions such as an ovarian cyst with twisted pedicle or a ruptured gastric ulcer will seldom need differentiation from ectopic gestation. The history or results of biologic tests for pregnancy will usually make the diagnosis definite.

Summary—When a woman has a skipped, delayed, prolonged or otherwise anomalous menstruation, a bloody, dribbling, brownish-red discharge accompanied by cramps, sudden sharp stabbing pains recurring on one side of the pelvis and an enlarged soft

Fig. 692.—Composite transverse section of an interstitial pregnancy brought by the artist to one plane. Note particularly the true decidua in the uterus, the funnels at the two torn ends of the interstitial tube, the complete tracing of the intramural tube from the uterine cavity to the isthmus and the hemorrhage in the ovum capsule and the uterine decidua.

there is a bulging cul-de-sac with leukocytosis and a normal sedimentation rate which is decreased in ectopic gestation. A diagnosis of ectopic gestation is quite certain when there is moderate fever, leukocytosis, great pain on moving the cervix and an exquisitely tender, pulsating mass behind or to one side of the uterus.

Pelvic Infection—In inflammatory disease there may be a history of gonorrhea with positive smears or postabortal infection, but there are no subjective signs of pregnancy. Biologic tests for pregnancy are negative and there is no vaginal bleeding or menstrual abnormality. In ectopic pregnancy the uterus is enlarged and leukocytosis is constant but likely to be higher in inflam-

matory disease. If puncture of the vaginal vault shows blood, an ectopic pregnancy is probable. If there is an exquisitely tender mass at one side or back of the uterus and if there is moderate fever and leukocytosis, a diagnosis of tubal pregnancy is justifiable.

Ray Diagnosis—In early cases uterine salpingography with iodized oil may reveal a defect at the site of implantation. Biologic pregnancy tests will only be positive when the ovum is alive.

Interstitial Tubal Gestation—Implantation in the intramural tube differs from gestation in the free tube only because of the

• Nelson's Loose-Leaf Surgery. Thomas Nelson and Sons, Publishers.

differing anatomical conditions which modify its progress e.g. the interstitial tube has little muscular wall hence the ovum almost immediately becomes embedded in the uterine wall which resists rupture much longer than the free tube but it rarely avoids rupture beyond the sixth month of gestation when there is violent pain and bleeding. If a soft mass is felt at one uterine cornu with the usual characteristic history of ectopic pregnancy the diagnosis of interstitial pregnancy is justifiable.

Ovarian Pregnancy—Formerly it was believed that ovarian implantation occurred only in the burst follicle. Further investigation (Stux and Gertscl) proved that nidation occurs in the following ovarian locations:

- 1 *Intrafollicular* the most common
- 2 *Superficial* Rarely nidation may occur on the ovarian surface because of furrows sulci or superficial endometriosis
- 3 *Suprafollicular* also rare A blood clot holds the ovum at the opening of the burst follicle where it is fertilized becomes implanted and develops
- 4 *Interstitial* exceedingly rare Theoretically the ripe follicle bursts inward because of a tough capsule when it finally ruptures outward the spermatozoon fertilizes it in the interstitial part of the ovary where it develops

A hematoma of the ovary frequently is due to an ovarian pregnancy but may be due to a ruptured lateral cyst, leukemia, phosphorus poisoning, acute torsion or endometriosis. The symptoms are essentially the same as in tubal pregnancy for which it is usually mistaken.

Abdominal Pregnancy—*Primary*—Although the possibility of primary implantation into the peritoneum has long been denied enough authentic cases have been reported to prove this bizarre possibility.

Secondary—This happens when a live embryo escapes from its primary location into the abdominal cavity the placenta retains its original attachment and the fetus continues to develop sometimes even reaching full term. Operation at full term may yield a living child which is frequently de-

formed. When the condition is not recognized at full term a short false labor occurs the fetal circulation stops and the placenta degenerates and is often completely absorbed.

There is much discomfort fetal movements are more active and the fetal heart tones, funic souffle and uterine bruit are more distinct. The fetus seems to be directly under the abdominal wall with the uterus to one side of it. While the fetus may survive it usually dies long before term and degenerates by maceration, adipocere or lithopedion formation.

Treatment of Extrauterine Pregnancy—There is no justification for expectant treatment of ectopic pregnancy. Too many patients die while the physician waits for recovery from shock which may never transpire. Even in the presence of shock due to hemorrhage very few patients die as a result of immediate operation by one skilled in the procedure. The laissez faire policy is most hazardous. Those who advocate waiting recovery from shock lose precious time and more precious blood. There can be no safety until the bleeding vessels are tied. Immediate operation does not mean ill timed hurry but a deliberate rapid preparation for operation under as favorable conditions as possible. Simultaneously shock must be combated by rest, morphine and dried blood plasma given slowly.

Before rupture the prompt removal of the gestation is urgently indicated. The ease and good results of this procedure emphasize the necessity for early diagnosis and prompt operation.

During rupture there is blood in the peritoneal cavity and consequent fever, leukocytosis and pain catastrophe impends though the tube has not yet burst. Immediate operation is imperative to avoid further bleeding, shock and collapse.

After rupture when there is often collapse due to alarming hemorrhage there is no assured safety until the bleeding artery is tied. Transfusion of blood has been one of the greatest factors in limiting mortality in ectopic pregnancy. Unfortunately in smaller communities blood donors or blood banks are often not readily available.

The development of the preparation of

dried blood plasma and its extensive and successful use with our wounded soldiers opens up additional resources for the treatment of these hemorrhagic tragedies in civil war life. The smallest hospital now has available life saving plasma which requires no blood grouping and can be easily and quickly given to tide over any emergency at least until a transfusion can be given. Any hospital or physician can now have a plasma bank.

Operative Technique—Only such blood as may interfere with exposure of the source of the bleeding should be removed; then hemostasis is secured by means of clamps or digital pressure followed by secure ligation. The ovary should be quickly isolated so that it will not be removed with the tube.

The removal of the entire tube with a wedge of the uterine horn will prevent a second ectopic implantation in the stump of the removed tube, several cases of which have been reported. All blood should be left in the abdomen as it will be absorbed rapidly to the great benefit of the patient and will not cause adhesions.

In early interstitial pregnancy the mass may be removed from the uterus but in more advanced cases hysterectomy may be necessary.

Treatment of Abdominal Pregnancy—When the fetus is alive and the mother is in good condition laparotomy may be postponed until the thirty-eighth week in the interest of the fetus. Although it may be deformed a sufficient number are normal to warrant delay.

The treatment of the placenta is most important because of danger of hemorrhage. If the fetus has been dead for sufficient time the uterine sinuses are already thrombosed so that the placenta may usually be removed without causing alarming bleeding. If however fetal death is quite recent or the fetus is alive at the time of operation it is exceedingly dangerous to attempt to remove the placenta because of the danger of excessive bleeding. If one feels sure that there is no infection Beck advises tying the cord short and cutting it leaving the placenta and closing the abdomen without drainage. By an older method if one is not sure of asepsis the membranes may be sutured to the abdominal wall the cavity

loosely packed with gauze and the placenta permitted to drain away slowly.

Mortality—Modern scientific methods have reduced the mortality of ectopic pregnancy from around 90 per cent before Lawson Tait's first operation to 2 or 3 per cent. In a series of 1421 reports of cases collected by the writer from six teaching clinics the mortality was only 2.24 per cent. Ectopic pregnancy is a potential hemorrhagic catastrophe which nearly always without proper treatment kills the child and is also a tragedy for the mother. To have reduced the death rate so remarkably is a tribute to improved diagnosis to modern clinical and laboratory methods and to gynecological judgment and skill.

JENNINGS CLAWFORD LITZENBERG

ENDOMETRIOSIS

The term endometriosis was suggested by Simpson to designate a variety of adenomatous lesions found in the female pelvis which present histologic and functional characteristics of normal endometrium. It may be truly called a disease of theories for more suggestions as to the origin of these islands of ectopic endometrium have been offered than for almost any other phase of pelvic pathology. Cullen gave the first definite clue as to the true significance of their origin when he proved that the glandular phases of adenomyomas were derived from the endometrium. The earlier authorities attributed them to adult remains of the wolfian system, inclusions of müllerian rests, the influence of inflammation on the endothelial cells of the peritoneum causing them to be transformed into cuboidal or cylindrical cells and metaplasia or the effect of inflammation by which the cuboidal cells of the germinal epithelium are transformed into cylindrical epithelium which resembles mucosa. The implantation theory recently proposed by Simpson is now more widely accepted than any of the earlier theories. Sampson evolved his theory after an exhaustive study of perforating hemorrhagic cysts of the ovary and proved that misplaced endometrial tissue wherever found is a histologic structure identical with that of uterine mucosa and is governed by the same physiologic factors as the mucosa of the

uterus Uterine or tubal epithelium may escape into the peritoneal cavity during menstruation and these regurgitated fragments spill into the pelvic cavity lodge on the various structures (having a special predilection for the ovaries) become implanted and eventually develop into adenomatous growths that respond to the stimulus of the ex hormones as does the normal endometrium These adenomatous islands may develop into hematomas filled with menstrual blood or they may remain as small super

the myometrium by endometrium is seen fairly frequently It occurs usually in the middle-aged women and often is the cause of menorrhagia The uterus may be a little enlarged the enlargement usually involving the posterior wall Treatment is surgical

Sum p on s conclusions are still the subject of much controversy but there is no doubt that he has proved the definite origin of a large group of ectopic endometrial lesions not explained by any other theory and has at last proved the identity and physiologic

Fig 693—Perforation of orthogastrium of both ovaries. Illustration of the posterior wall of the uterus. Posterior view of the uterus and ovaries (natural size). At operation both ovaries were adherent to the posterior surface of the uterus. The left ovary is partially collapsed owing to the escape of the contents of the cyst. The raw area with perforation in the center is shown. The contents of the hematoma of the right ovary were thicker than those of the left and are indicated as coming from the perforation. At and about the surface of the uterine wall which was adherent to the left ovary can be seen slight elevations (1) which proved to be superficial adenomas. Adenoma of the endometrial type as found developing between the adherent right ovary and the surface of the uterine wall at A. Sections were taken from other portions of the uterine wall and the ovaries (four).

ficial red or purplish elevations on the pelvic structures. On the other hand their invasive tendencies may lead to deep involvement of the ovaries causing the formation of cysts which are filled with old menstrual blood commonly called chocolate cysts.

The gradual increase of the contents of the cyst leads to perforation of the cyst wall with a second dissemination of endometrial tissue for further implantation in the cul de sac rectovaginal septum rectum and uterine wall. Adenomyosis a benign invasion of

characteristics common to müllerian tissue wherever located.

Pathology.—The microscopic picture of endometrial lesions wherever found is fairly uniform. The glands are lined with a single layer of cuboidal or cylindrical epithelium with darkly stained centrally placed nuclei. Endometrial hematomas of the ovary vary in size from minute superficial lesions involving only the surface of the organ to large cysts measuring several centimeters in

diameter. The small cysts are recognized as small red or purplish bodies on the surface of the ovary, the color depending on their age and the period of the menstrual cycle. The implants may affect only one ovary, although both are usually involved. The larger growths have their origin deep within the substance of the ovary. As the adenomatous lesion responds to the ovarian stimulus, bleeding occurs and cyst formation results. Perforation eventually occurs, the irritating contents are widely disseminated in the pelvis, causing secondary transplants that have more invasive tendencies than the original transubal epithelium. Sampson believes that the ovary acts as a hotbed for the

associated pathologic findings are important from a diagnostic standpoint. The frequent incidence of endometriosis as a complication of fibroids of the uterus is striking, nearly one half of the cases will be found associated with fibroids. Retrodisplacements of the uterus and chronic pelvic inflammatory disease rank next in frequency.

Next to perforating hemorrhagic cysts of the ovary, the most characteristic lesion is endometriosis or adenomyoma of the rectovaginal septum. The growth usually presents as a diffuse nodular thickening in the vaginal vault, which frequently involves and fixes the cervix as well. Cullen's classification is authoritative:

Fig. 691.—Cross section of the uterus and ovaries (natural size) illustrating the condition found at operation. Both ovaries were adherent to the posterior surface of the uterus; it is seen that the perforations. The adenoma has spread over the surface of the uterus and was just beginning to invade it. The relation of the rectum to the uterus is indicated by the dotted lines. The larger adenoma (c) of the left ovary is shown in longitudinal section and also the smaller one (e) of the right ovary, with the graafian follicle cyst lateral to it. Sections of the uterine wall failed to show any endometrial tissue between the superficial growth on its posterior surface and the mucosa of the uterine cavity.*

primary implants and that the secondary growths possess more active properties through having become accustomed to their environment. Whenever perforation occurs, the opening is promptly sealed or walled off by the adjacent structures and the adhesions that result become so dense and fused that the type is characteristic. Beneath these dense peritoneal adhesions, adenomyomas in violation of the deeper structures of the intestinal wall, rectum, rectovaginal septum and uterus may be found. It then becomes an infiltrative rather than a destructive process. Only the ovary produces the larger destructive cysts and the adhesions about them are so dense, owing to the infiltration of the underlying tissues that removal without rupture is practically impossible. The

- 1 Small adenomyomas lying free in the rectovaginal septum.
- 2 Adenomyomas adherent to the posterior surface of the cervix and at the same time to the anterior surface of the rectum.
- 3 Adenomyomas gluing the cervix and rectum together and spreading out into one or both broad ligaments.
- 4 Adenomyomas involving the posterior surface of the cervix, the rectum and the broad ligaments and forming a dense pelvic mass that cannot be liberated.

Other typical lesions are those found in the inguinal canal, the round ligaments, the umbilicus and laparotomy scars.

*Sampson, Arch. Surg. 3.

Symptoms.—Endometriosis may be a slow and insidious disease. Amazing destruction may take place with few if any symptoms to point to its presence. As a rule the symptoms are progressive and depend largely on the complications. Pain usually dull and aching in character localized low in the abdomen and back and always aggravated during the menstrual period is frequently emphasized. Acquired dysmenorrhea is very suggestive menorrhagia and metrorrhagia appear in about one half of the cases and dyspareunia is more common than any of the other symptoms. There is nothing really characteristic in the symptoms by which a diagnosis can be made. Keene insists very correctly that it is not a single symptom but rather the symptom complex that aids in making a differential diagnosis and he emphasizes the following points: (1) age between twenty-five years and the menopause (2) sterility absolute or relative (3) abnormal menstruation usually menorrhagia (4) dysmenorrhea as the acquired type (5) dyspareunia (6) sacral backache (7) intermenstrual lower abdominal pain with increased discomfort at the time of menstruation and (8) pain in the rectum or bladder which bears a distinct relation to menstruation.

Diagnosis.—The majority of the cases of endometriosis are not recognized before operation. The usual diagnosis is chronic pelvic infection or fibromyoma of the uterus associated with diseases of the appendages. Vaginal examination reveals a tender densely adherent semi-solid or firm nodule mass. The uterus is retrodisplaced and adherent. The only distinctive lesions are the nodular fixed masses which are palpated in the cul-de-sac. Rectal examination should always be made as it reveals more evidence than vaginal palpation. Proctoscopic examination is of distinct value in differentiating a malignant growth. The rectal mucosa overlying the nodular masses is normal in endometriosis but rarely so in carcinoma. Nodular areas in the vaginal vault often show the tell tale red or purplish spots and are conclusive evidence when found. The rectovaginal septal lesions may exist without ovarian invasion but in outlining treatment it must be remembered that both are more frequently involved. There are no

characteristic symptoms in widely situated lesions such as in the mabilians. Laparotomy scars and the inguinal canal other than the exaggeration of symptoms and occasional bleeding during menstruation. Green Armytage has found injections of milk of value in differentiating between chronic pelvic infection endometriosis and pelvic tuberculosis. He insists that the reaction following these injections which commonly occurs in infections does not occur in endometriosis or tuberculosis. The condition has been confused with pelvic tuberculosis. Green Armytage emphasizes the value of the von Pirquet test when tuberculosis is suspected.

Prophylaxis.—Endometrial growths according to Sampson rank in frequency next to uterine myomas. If transubal implantation is the method of dissemination rough pelvic examinations during or near the onset of menstruation and tubal insufflation as well as operations too soon after menstruation may figure as exciting factors in the transportation of the endometrial cells.

Treatment.—The activity of all endometrial growths depends on ovarian function. When menstruation ceases retrogressive atrophy of the lesions follows. In this lies the keynote to successful treatment. The treatment is essentially surgical. In women forty years of age or more the problem presents no perplexities—removal of the ovaries releasing adhesions and often hysterectomy are indicated. In younger women conservative measures must be followed. Too often radical operation is necessary but small chocolate cysts may be removed by resection at the cul-de-sac, one ovary may be saved small lesions on the intestinal wall or mesentery may be cauterized and complete function may be restored. The tubes are usually patent and 28 per cent of Keene's patients subsequently bore children. Unfortunately many patients may require a secondary operation and if extensive endometriosis is found at operation removal at least of both ovaries is indicated. This applies as well to extensive infiltration of the rectovaginal septum and more particularly to involvement of the rectum. In many of these cases the patient has been subjected to radical resection of the intestine under a mistaken diagnosis of cancer.

Radium and x-ray treatment are rarely

indicated. Conservation of the ovaries should always be attempted when possible and irradiation will not remove adhesions and chocolate cyst collections. Furthermore it is too difficult to differentiate between endometriosis and chronic pelvic infection to run the risk of lighting up a latent disease which is so likely to occur after irradiation.

BENIGN LESIONS OF THE CERVIX

INFLAMMATION OF THE CERVIX*

The cervix is prone to infection because pathogenic and non pathogenic bacteria are always present in the vagina. No habitat is more inviting to the gonococcus than the columnar epithelium of the endocervix and underlying racemose glands. The resulting infection causes swelling and edema which narrow the cervical canal and prevent proper drainage. Infection plus poor drainage always leads to more extensive and deeper inflammation. The cervix has been called the tonsil of the vagina because of the similarity in the behavior of the two structures. Chronic endocervicitis is one of the most common gynecological lesions.

Etiology—Endocervicitis may be caused by (1) gonorrheal infection (2) postabortal and postpartum infections with or without lacerations (childbirth instrumentation

etc) (3) cervical trauma from any cause plus infection and (4) hematogenous infection.

Acute Endocervicitis—Acute endocervicitis is not commonly observed because by the time the patient is first seen the acute stage of the inflammation has passed.

Pathology—The endocervix and to some extent all the cervical tissues are reddened and edematous. There is a mucopurulent or purulent discharge. Microscopically there is an acute inflammation, i. e. edema, round cell infiltration and engorgement. The columnar epithelium of the mucous membrane of the endocervix as well as the squamous epithelium about the external os shows degenerative changes.

In acute endocervicitis particularly if gonorrheal there is danger of upward extension into the uterine cavity and thence to the fallopian tubes, ovaries and peritoneum. If the cause is the streptococcus, staphylococcus, *B. coli* or some other pathogenic bacterium or a mixture of these extension is largely through the lymphatics to the parametrium then to the peritoneum, fallopian tubes and ovaries.

Symptoms—In acute endocervicitis systemic symptoms are absent or slight. There may be general malaise, lower pelvic discomfort and backache. Purulent or mucopurulent leukorrhea is always present. Often if the infection in the cervix is coincident with vaginal or pelvic infection or trauma or both the symptoms of these predominate.

Diagnosis—Inspection reveals the presence of a copious discharge. If gonorrheal suspected examination of smears confirms the diagnosis. When the acute stage has subsided examination can be made more satisfactorily and with less trauma.

Treatment—Rest in bed with promotion of drainage and cleanliness are paramount. For cleansing purposes a warm alkaline douche is invaluable. It should consist of from 2 to 4 quarts of warm water with half an ounce of bicarbonate of soda or any alkaline agent several times a day alternating with 1:5000 potassium permanganate solution when the diagnosis of gonorrhea is certain. Topical applications are used but little today as they are somewhat traumatic and often do more harm than good. If the cause is gonorrheal in origin sulfathiazole in full

* Endocervicitis and cervicitis will not be differentiated in the discussion of clinical folkways.

the cases in group 1 and 2 and the upper half of group 3 may be successfully treated with the electric cautery. In cases in the lower half of group 3 and all of group 4 cautery treatment is contraindicated, the

procedure being repeated on the opposite lip two weeks later. In order to promote healing and minimize further infection 4 per cent mercurochrome is copiously ap-

* Matthews JAMA 87

plied to the cervix and vagina. A daily alkaline douche is ordered. Further cauterization may or may not be needed.

In the nulliparous non-eroded cystic cervix the wire cautery tip should be used for puncturing the cysts and stripping the mucous membrane (Fig. 696).

The technique of the Sturmdorf operation with certain modifications is as follows. With the patient in the lithotomy position the anterior and posterior lips of the cervix within the margin of the erosion are grasped and the cervix is pulled down. An incision is made through the mucous membrane of the portio encircling the outer limits of the eroded area. The mucosa of the portio is dissected back for a distance of 2 or 3 cm. or more to obtain sufficient mucous membrane to cover the excised area completely (Fig. 697). With a scalpel the entire gland-bearing area of the cervical canal is coned out, the excision extending to or just below the internal os (Fig. 698 A). Great care should be exercised so as to preserve the muscle tissue and remove the infected area. If too much cervical (muscle) tissue is removed the operation becomes an amputation (high or low) but this should be avoided. If not enough tissue is removed and the infected glands are left the operation will be a failure. Lateral sutures two on either side are next placed at strategic points (Fig. 698 B) and held as traction sutures. The final step of the operation is to cover over with the loose vaginal cuff the funnel-shaped cavity left by the removal of the cervical cone. There should be ample cuff to insure good apposition without tension which is chiefly accomplished by a double inverting stitch (Figs. 699 A and B and 700) passing through both anterior and posterior lips of the newly formed cervix. With all six sutures tied thorough coaptation of the vaginal cuff is obtained and complete hemostasis is accomplished (Figs. 701 and 702). A small strip of mercurochrome gauze drain is placed against the cervix. This should be removed in twenty-four hours.

Other methods recommended in the treatment of chronic endocervicitis are the following:

Diathermy.—Cherry, Corbush and O'Connor, Ward and others are enthusiastic over

their results obtained with diathermy. A therapeutic temperature of from 109° to 113° F. may be attained in the cervix and this is lethal for gonococci. Generally heat in chronic pelvic infections relieves pain, diminishes pelvic masses and aids in complete resolution.

Coinization.—This was introduced by Hyams of New York. The diseased endocervix is excised by means of a fine, smooth high frequency current. End results are excellent but the apparatus which is employed is expensive.

Radium.—Irradiation has been recommended but is not advised for the following reasons: (1) It may produce acute exacerbation of a chronic inflammation. (2) It may have a deleterious action on the ovaries, sometimes even after a small dosage and (3) it tends to produce stricture of the cervix.

SYPHILIS OF THE CERVIX

Reliable reports of syphilis of the cervix are rare. Gelhorn and Ehrenfest in 1916 published their excellent work on syphilis of the generative tract and their description of syphilis of the cervix is standard. According to these authors cervical chancre is rare. The lesion contains many spirochetes and the diagnosis is made by a dark field study of smears. The Wassermann reaction at this stage is negative.

Secondary syphilis of the cervix occurs as condyloma latum and is readily recognized. The Wassermann reaction is positive. Secretions contain many spirochetes.

Tertiary syphilis of the cervix is said to be most common. The lesion is a yellowish ulcer with indurated edges which secretes a profuse yellowish discharge (gumma). Spirochetes are present in the secretions and curettings from the base of the gumma. The reaction to the Wassermann test is positive.

Symptoms.—There is nothing pathognomonic but syphilis may be suspected on examination. A history of contact is helpful. Secretions and curettings from the ulcerated areas reveal the *Spirochaeta pallida*.

Treatment.—General antisyphilitic treatment is indicated and is curative. Cauterization, electrocoagulation and surgical treatment are contraindicated.

TUBERCULOSIS

Tuberculosis of the cervix is very rare. Generally it is secondary to tuberculosis of the endometrium and/or endosalpinx. It appears as an ulcerated area about the external os or in the cervical canal as an easily bleeding papillary mass near the os or as military tubercles scattered over the cervix. A positive diagnosis can be made only by biopsy.

Symptoms—There are no characteristic symptoms. Leukorrhea is usually present. If tuberculosis exists elsewhere its symptoms are present.

Treatment—High amputation of the cervix should be performed if the lesion is not extensive. Electrocoagulation has been recommended. If the extent of the tuberculous process is doubtful panhysterectomy is indicated. The general treatment of tuberculosis is essential.

Actinomyces echinococcus and bilharzia infections of the cervix are extremely rare. Actinomyces is probably more common than is generally supposed (Graves) because it is easily confused with gonorrheal or tuberculous infection.

CONDYLOMA ACUMINATUM

A condyloma acuminatum (moist wart) of the cervix is usually associated with gonorrheal infection but may occur with any persistent irritating discharge. The condylomas occur singly or in groups on the vaginal portion of the cervix and are to be distinguished from the condyloma latum of secondary syphilis.

Treatment—Cleanliness is important and an alkaline douche once or twice a day is useful. The warts may be destroyed by fulguration, the electro-surgical knife or the actual cautery. A chemical escharotic, e.g. formalin or trichloroacetic acid may be used. The application of vaselin serves to prevent injury to the surrounding tissues. Local anesthesia is usually indicated before mass removal. The use of 4 per cent solution of mercurochrome or sulfanilamide powder promotes healing and minimizes the likelihood of further infection.

STENOSIS OR STRICTURE AND ATRESIA OF THE CERVIX

Stricture or atresia of the cervical canal may be congenital or acquired (usually ac-

quired) and may be located in any part of the cervical canal from the internal to the external os. Atresia is frequently found at the external os.

Etiology—Deep seated virulent infections of the endocervix, trauma incident to inappropriate topical treatment, extensive cauterization, poorly executed operations and trauma of childbirth may cause stricture (stenosis) or atresia or both. Atresia frequently follows scalpel or electro-surgical amputation of the cervix and irradiation for chronic infection or carcinoma of the cervix. Elderly women after the menopause are likely to have atresia.

Symptoms—The symptoms vary depending on whether the cervix is partially or completely closed. Leukorrhea is the outstanding symptom of stricture. Atresia causes hematometra, the symptoms being similar to those in amenorrhea—severe menstrual pain or constant abdominal pelvic pain, lower abdominal tumor and general debility. Hematosalpinx with leakage of blood into the peritoneal cavity may be the end result of hematometra and may cause peritoneal irritation with pain, rigidity, tenderness over the distended uterus, fever, rapid pulse, etc. In the aged pyometra is occasionally encountered.

Prognosis—The prognosis is good if drainage through the cervix can be secured and poor if the symptoms are severe and it is necessary to resort to anterior hysterotomy or hysterectomy.

Treatment—Treatment consists of dilation of the cervix with or without anesthesia. A small uterine sound or small uterine dressing forceps is introduced past the stricture or stenosis or atretic area. When this cannot be accomplished thorough dilation of the cervix should be attempted under anesthesia. If this cannot be accomplished anterior hysterotomy or hysterectomy should be performed.

CERVICAL POLYPS

Cervical polyps are of two types: (1) glandular and (2) fibrous. The glandular type of polyp is the result of an inflammatory outgrowth of the cervical mucous membrane and is the more common. The fibrous type arising from the musculofibrous portion of the cervix appears as a small pedunculated fibroma hanging through the external os.

Etiology—The mucous type of polyp is the result of a chronic inflammatory outgrowth of the cervical mucous membrane or of the corporeal endometrium. The fibrous polyps apparently occur in the same patients as do fibroid tumors and consequently little is known of their cause.

Pathology—The glandular polyp may be single or multiple and appears as a small bright red growth at the external os. It is covered with columnar epithelium or partly with columnar and partly with squamous epithelium and consists of a vascular connective tissue stroma containing many racemose glands. Usually there is chronic inflammation. The fibrous polyp is also covered with columnar and/or stratified epithelium containing fibrous or muscle tissue richly supplied with blood vessels.

Symptoms—Polyps often slough in the dependent portion and intermenstrual bleeding (metrorrhagia) is common. Spotting following coitus is also frequent. Leukorrhea streaked with blood may be present. Larger polyps, particularly the fibroid type, often cause menorrhagia.

Diagnosis—The diagnosis is simple and is made on inspection.

Treatment—Smaller polyps may be removed in the office with the actual cautery or electro-surgical knife with no fear of subsequent bleeding. Simple ligation of the pedicle and excision of the proximal portion of the polyp will suffice, but subsequent recurrence is more frequent. Larger or sloughing polyps should always be examined for malignant changes.

When anesthesia is used for other operations, dilation and curettage of the uterus and cervix will remove all polypoid growths. When the polyps are large they may be removed by anterior hysterotomy. In elderly women radium may be used to destroy the cervical mucous membrane and prevent recurrence. In such cases the cervix should be repeatedly dilated in order to prevent stricture.

SURGICAL LESIONS OF THE VAGINA

Among the more common surgical lesions of the vagina are those resulting from traumatic injury. Before marriage there occasionally occurs the injury coincident with forceful coitus—not always rape—and the injury that results from external violence such as falling astride a chair or sharp pointed object for instance a pocket fence or ornamental post traumatizing the vagina in varying degrees. Occasionally the urethra, bladder or rectum also is injured. After marriage injuries due to childbirth—rectocele, cystocele and prolapse—are common lesions.

Acquired atresia or stenosis (complete or partial closure) of the vagina occasionally occurs as the result of extensive traumatic injury followed by infection and scar formation. Extensive ulcerations from any cause notably escharotic chemicals used in douches or suppositories, malignant and syphilitic ulcerations, extensive inflammatory processes and more commonly adhesive senile vaginitis of the aged may cause atresia of the vagina.

Treatment—The management of a traumatic injury of the vagina other than that due to childbirth depends on the character and extent of the wounds. A small wound needs only to be sutured after all bleeding

has been controlled. A large laceration may require an extensive plastic operation. When there is also injury to the urethra, bladder or rectum the problem becomes more complicated and calls for delay in operation in order that asepsis may be obtained. The most important requisites for a successful plastic operation are hemostasis and asepsis. Since the advent of the sulfa drugs infections are less troublesome. From 5 to 8 mg of the appropriate sulfonamide may be sprinkled into the wound as a prophylactic. If in spite of all prophylactic measures infection sets in chemotherapy with the appropriate sulfa drug is indicated in full therapeutic dosage. Every plastic surgical operation should be successful in the absence of infection while in its presence complete or partial failure is almost certain to follow. (See section on General Principles of Plastic Surgery.)

In general in repairing a wound in the vagina the surgeon should make every effort to leave the least amount of scarring possible and to reestablish the normal vaginal orifice as accurately as possible. Scar tissue makes for painful coitus and dispareunia causes unhappiness in many families.

In the treatment of atresia of the vagina the method of approach will be determined by the cause. Dissection of the dense scar tissue with plastic restoration of the vaginal canal is usually all that can be done. When the atresia is the result of severe senile vaginitis in an elderly woman separation of the adherent surfaces by blunt dissection followed by a light iodoform pack usually suffices. The walls of the vagina must be kept separated for twelve to fourteen days or longer in order to prevent reformation of adhesions. This can be accomplished by placing sterile rubber tissue or the cuff of a rubber glove properly shaped in the vagina after the removal of the original iodoform pack. The rubber tissue form should be replaced every few days at which time the vaginal canal may be sprayed with a suitable germicide (4 per cent mercurochrome). Immediately after operation an estrogenic hormone should be given intramuscularly in large doses (10,000 units) daily or twice weekly to stimulate epithelial growth over the impoverished vaginal mucous membrane. Results are uniformly good.

Lacerations resulting from childbirth and manifested in the form of rectocele, cystocele and prolapse are discussed elsewhere. (See section on Displacements of the Uterus.)

Cysts—Cysts of the vagina are relatively rare. They may be either congenital or acquired.

A congenital cyst of the vagina may arise from an embryonal rest from the remains of Gartner's duct (vaginal portion of the Wolffian duct) and/or the müllerian duct.

An acquired cyst of the vagina may arise (1) from an aberrant vaginal gland (2) from an inclusion of epithelium after an operation on the vagina, traumatic injury or laceration due to parturition (3) or after an abscess of Bartholin's gland or (4) rarely it may be due to a dermoid or celinococcus cyst. A vaginal cyst may be small (the size of a pea) or very large filling the vagina. Occasionally such a cyst becomes pedunculated and delivers itself out of the vagina. It is usually spherical or oblong but owing to pressure or other external forces it may become elongated or cylindrical or may assume some other unusual shape.

Symptoms—A vaginal cyst usually produces no symptoms unless it attains sufficient size to interfere with coitus or unless it becomes infected. Infection is extremely rare but when it is present the usual symptoms of acute inflammation appear. If the cyst grows to considerable size symptoms caused by pressure on the bladder, urethra or rectum may appear. If pregnancy occurs such a cyst may prevent or retard the descent of the presenting part during labor and delivery.

Treatment—Excision is the only effective treatment for a cyst of the vagina. Mere incision and aspiration of fluid is not curative. In rare instances and under unfavorable circumstances (infection or emergency) incision and cauterization of the site followed by packing with iodoform gauze may accomplish the desired result. When the cyst or cysts are situated high up in the vaginal vault and perhaps extend up between the layers of the broad ligament (embryonal cysts) extirpation may become extremely difficult and may be attended with considerable danger to the patient (e.g. injury to important pelvic structures such as large

blood vessels bladder ureter rectum or pelvic peritoneum)

The prognosis is good in all cases in which the cyst wall is completely removed. In excision only with or without cauterization of the sac and with packing of the cavity with iodoform gauze is likely to be followed by recurrence of the cyst.

NEW GROWTHS

Benign Growths—A fibroma, fibromyoma, adenomyoma or endometrioma occasionally develops in the vaginal wall. If it is of sufficient size to produce symptoms, extirpation is the proper treatment. Before attempting extirpation, however, one should be sure of the diagnosis, since a fibroid or vaginal hernia might be mistaken for a soft myoma or endometrioma. (See section on Endometriosis.)

A venereal wart (condyloma) in the vagina usually occurs as an extension of such a growth from the vulva and is associated with gonorrheal infection. It may occur also on the vaginal portion of the cervix. It is to be distinguished from condyloma latum of secondary syphilis. Excision in the office or hospital with the actual cautery or radio-knife or by fulguration is the method of choice in removing these growths. Excision with the scalpel may be done when the aforementioned modalities are not available. Hemorrhage must be controlled. Local anesthesia is usually all that is required. The generous use of 4 per cent mercurochrome or some other antiseptic minimizes the chances of infection.

Malignant Growths—Primary carcinoma (squamous cell type) of the vagina is extremely rare. Secondary or metastatic carcinoma of the vagina may occur from any malignant growth in an adjacent pelvic structure, the cervix being the most common site of the primary carcinomatous lesion. Vaginal extension from a vulvar or rectal carcinoma is commonly encountered. The inguinal and pelvic glands are invaded early. The prognosis is accordingly bad unless diagnosis is made early and proper treatment is carried out.

Symptoms—Symptoms of the metastatic growth are those of the primary lesion (see section on Malignant Tumors of the Uterus) plus a watery, fetid discharge which may or

may not be bloody. Pruritus is usually present. Bleeding may later become excessive. Pain is likely to be a late symptom.

Diagnosis—The diagnosis is based on the physical characteristics of the growth (friability, bleeding on the least manipulation and infiltration) and microscopic examination of a biopsy specimen.

Treatment—The treatment of the primary lesion is fully discussed elsewhere. (See sections on Malignant Tumors of the Uterus, Carcinoma of the Vulva, Carcinoma of the Rectum and Anus.) Treatment of the primary vaginal growth is that of the malignant growth elsewhere in the pelvis. If it is localized early, complete radical extirpation is indicated; if extensive and if metastasis has occurred, irradiation is better (radium and/or deep x-ray). In operative cases, irradiation after excision is always in order. Some authorities advocate irradiation both before and after operation. With either method, irradiation must be adequate over a period of from three to five years and at definite intervals. Here as elsewhere in the treatment of cancer, eternal vigilance is the price of success.

Sarcoma—Primary sarcoma of the vagina is extremely rare. In adults the growth may be anywhere in the vaginal canal. In children the vaginal cylinder is found to be filled with a polypoid grapelike mass which may have a basic attachment to any portion of the canal but according to good authority the attachment is more frequently to the anterior wall. Supposedly these primary growths in children and young adults originate in embryonal rests. These growths are highly malignant and of rapid growth and are frequently well advanced before advice is sought. There is rapid extension to the bladder, parametrium and pelvis generally. Metastasis to distant organs renders the prognosis uniformly bad.

Symptoms—Vaginal discharge which may be sero-sanguineous, mucopurulent, bloody or blood streaked and which has a fetid or foul odor and later frank hemorrhage are suggestive. Pain may or may not be present. Microscopic examination of a biopsy specimen establishes the diagnosis.

Treatment—The treatment is the same as that for carcinoma of the vagina. Secondary or metastatic sarcoma from structures

near or in juxtaposition to the vagina may occur. The symptoms and treatment are the same as those of the primary growth.

Chorioma, or Chorionepithelioma—Chorioma or chorionepithelioma of the vagina may occur although rarely as a metastatic growth or as a transplant from chorioma of the uterus (See section on Chorionepithelioma).

INFLAMMATION (SURGICAL)

Tuberculosis—Tuberculosis of the vagina rarely occurs as a primary lesion but is more frequently secondary to tuberculosis higher up in the reproductive or genitourinary system (e. g. uterus oviducts bladder ureters or kidneys). Because of this the posterior wall of the vagina is the most common location of the lesion.

Symptoms—The lesion usually appears as an ulcer in which tubercles may be identified. Later confluent ulcers make their appearance and thus extend to surrounding structures such as the bladder and rectum. There is little or no pain. The discharge is seropurulent and later perhaps blood stained. This lesion must be differentiated from a malignant or syphilitic ulcer.

Treatment—Destruction of the ulcer or ulcers with the actual cautery is recommended when the lesion is single and small. When it is extensive, excision is the procedure of choice. Irradiation (x-ray or radium) has been used with good success. If tuberculosis of the endometrium or fallopian tube exists panhysterectomy when feasible should be performed (See section on Tuberculosis of the Cervix).

FOREIGN BODIES IN THE VAGINA

Foreign bodies in the vagina e. g. a forgotten pessary, part of a broken douché tip, a large safety pin or any cylindrical object used in masturbating which remains *in situ* for a long period produces discomfort, pain and leukorrhea which is seropurulent, bloody, fetid or foul. Such symptoms may be mistaken for those of malignant disease and it is only after thorough investigation that the correct diagnosis can be made.

Treatment—Treatment consists in removal of the foreign body. Often this is easy with or without anesthesia. However it occasionally happens that the object inserted

is deeply embedded in the vaginal tissues and considerable damage may be done in its removal e. g. in one of the author's cases a ring pessary had remained embedded in the anterior wall of the vagina for nine years and when it was dissected free a large vesicovaginal fistula resulted. Many queer and formidable objects have been removed from the vagina in cases of insanity.

VAGINISMUS

Vaginismus is a spasmodic painful involuntary contraction of the muscles of the introitus (sphincter vaginae) and the lowermost segment of the vagina (anterior portion of the levatores ani). It appears most frequently in newly weds although it may occur in women who have borne children and not infrequently during or past the menopause.

Etiology—The cases of this condition fall into two groups: (1) those in which no cause is demonstrable and (2) those in which a definite cause is ascertainable. The underlying cause in all cases is undoubtedly neurotic in origin. However not infrequently there is coupled with this basic condition a urethral caruncle, an inflamed rigid hymen, an unhealed lacerated hymen or a vaginal or rectal fissure which aggravates the hyperesthesia of the vaginal orifice producing frank vaginismus. During or after the menopause atrophy of the external genitals and contraction of the introitus together with dryness of the parts a constant annoyance with the cessation of ovarian function often lead to a severe and intractable type of vaginismus.

Symptoms—Symptoms do not appear until coitus is attempted. Intercourse is found impossible. The hyperesthesia of the parts is so extreme that the lightest touch causes intense spasm and pain. The patient cries out, the thighs become strongly abducted and further approach is impossible. Examination by the physician is always trying and exasperating; indeed it is frequently impossible until complete anesthesia is induced. In the older and more experienced group the appearance of some pathologic lesion of the vulva, vagina or rectum plus a neurotic tendency associated with hyperesthesia of the parts causes pain and spasm on intercourse. During or after the menopause

pause atrophy contraction and dryness of the parts are responsible for fear and pain on intercourse

Treatment—The first step in treatment consists in allaying or removing the cause and the second is gradual and complete dilation of the vaginal orifice and lower segment of the canal. If there is no demonstrable lesion the administration of sedatives or hypnotics for the alleviation of the extreme nervousness and divulsion of the vaginal orifice under anesthesia will suffice. Occasionally in the mild case speculum stretching of the introitus and canal in the office or at home and immediate intercourse plenty of lubrication being used may effect relief. In severe cases even after removal of all visible causes coitus remains impossible or unsatisfactory. In such cases operation is imperative and is designed to enlarge the vaginal introitus. The Hirst operation is commonly employed. It consists in making a longitudinal incision in either side of the orifice (inside the skin line) and extending it for 2-3 or more centimeters up each vaginal sulcus incising the mucous membrane and superficial layer of underlying muscle (1 or 2 cm deep). These incisions are sutured transversely thus widening the vaginal entrance. Later when complete healing has taken place coitus can be accomplished without spasm or pain.

General hygienic measures sedatives and reassurance from the physician do much to relieve an otherwise disastrous situation particularly in the newly married. For women at or past the menopause sedatives and plenty of lubrication are the only means of treatment.

DISEASES OF THE VULVA

Vulvar symptoms and even vulvar lesions at times are of only secondary import to extension or spread from another site such as the vagina or cervix or even dermatological

lesions external to the labia. Some of the conditions which may require surgical treatment or a differential diagnosis from a therapeutic viewpoint will be considered in the following paragraphs.

HYPERTROPHIC STATES

1 Elephantiasis or Filariasis—The primary agent of filariasis is *Wuchereria bancrofti* (*Filaria bancrofti*). Streptococci or staphylococci may play a considerable role later according to Strong. Either the parasitic nematode or the bacteria alone or together cause a fluid and tissue reaction. In the broad sense different types of pathologic conditions may result from other species of the subfamily. Discussion here is restricted to the one type. Any obstruction to the lymphatic or circulatory system may cause enormous enlargement similar to that in filariasis. The labia may become greatly enlarged but is not comparable to the huge mass which occurs in scrotal growth. The tissue tends to be filled with lymphatic fluid and the dermis may take on a coarse pigskin effect. Labial edema as in heart failure or other passive congestion from pelvic abdominal or other local lesions or tumors may simulate early elephantiasis. These points and others must be considered in the differential diagnosis. Removal of the labial masses and at times portions of the mons veneris should be avoided during an active infectious state. Surgical removal is for rehabilitation in the broad sense. Until lately filariasis has been rare among the female population of the United States but there is increased likelihood of this condition among women who have served in areas where filariasis has been noted. Brown has reported on this in South Carolina and has noted the inguinal involvement in women.

2 Hernia—*Hernia of the vulva* is quite rare. However inguinal hernia has been known to descend along the inguinal or round ligament and canal of Nuck into the labia majora. *Hernia through the pelvic floor* is extremely rare. It may appear along the side of the vagina or may dissect down to the vulva directly. Intestinal obstruction may occur with either type of hernia. If bowel is in the area there should be definite tympany on percussion and other findings typical of hernia. It is improbable that omen

tum would descend as far as this Surgical correction is indicated for either or both of these types of hernia The repair must be directed toward replacement of the viscera and eradication of the ring through which the herniation occurred

3 Condyloma Acuminatum—At one time this condition was considered pathogenic of prior gonococcal infection However it is now recognized as a condition occurring under various circumstances and is not a stigma of venereal disease unlike condyloma latum Condyloma acuminatum tends to be a gradually growing lesion and although it is epithelial in origin it tends to be moist It is commonly associated with a foul odor and an altered bacterial flora The individual growth may be shaped like a pine tree It varies in diameter from a millimeter or slightly less to a conglomerate mass measuring many centimeters in diameter Numerous forms of therapy have had their proponents Freezing agents antiseptics drying or desiccating preparations ligation surgical excision cauterization or fulguration each has its favorable points Surgical excision of any appreciable amount of tissue may be associated with extensive bleeding and yet it does not prevent a recurrence Recurrences are likely to follow any type of treatment Wolters and Hesseltine have illustrated the value of the use of radium Dosages varying from 75 to 450 mg hr were employed in their series This small dosage of radium applied externally should not endanger the ovaries or the reproductive tract yet it was followed with various satisfactory results It is suggested that about 100 mg hr is an optimum dose for an area of 4 sq cm If the first application of radium is not followed in a few weeks by complete disappearance additional radium may be re-applied This method eliminates incision it is safe and it is simple Extensive condylomas about the vulva may be a serious complication at the time of delivery because of increased danger of hemorrhage and also because they favor the growth of abnormal bacteria which may predispose to puerperal infection Consequently treatment during pregnancy may be well indicated and at the same time radium would not entail extensive blood loss X-ray can be used but it is less easily restricted

4 Syphilis—*Syphilis* may manifest itself about the vulva as a *chancre condyloma latum or gumma* The diagnosis is confirmed by positive darkfield findings in the chancre or biopsy of the condyloma or gumma in which the classical histologic pattern will be found Serologic tests should be confirmatory for the latter conditions unless there has been adequate antiluetic therapy Surgical therapy is indicated only when adequate and proper antiluetic therapy has not been followed by reduction of the mass or sufficient improvement and if there are symptoms of sufficient magnitude Surgical removal may necessitate subsequent plastic reconstruction if there has been considerable deformity or destruction

5 Chancreoid—Chancreoid may produce enlarged inguinal glands which may suppurate and may be followed by chronically draining sinuses Kornblith Jacoby and Chargin used sulfathiazole and sulfanilamide The inguinal and vulvar glands associated with this infection should be protected from trauma and every precaution taken to prevent drainage Sulfonamides may be given during the active stage in an attempt to avoid suppuration Aspiration of the mass by passing a needle through normal healthy tissue and entering the area in directly or posteriorly may also have value Both surgical incision and spontaneous drainage are contraindicated for persistent sinuses follow frequently Once sinuses form they tend to persist and produce considerable cicatricial tissue Excision of these sinuses is frequently difficult

6 Granuloma Inguinale—Granuloma inguinale has somewhat the appearance of granulation type of tissue Torpin Greenblatt and Pund have reported on this condition It is encountered mostly in patients of poor hygienic type Surgical treatment is used only in the event that reconstruction or plastic procedures become necessary after the condition has been cured with suadim or antimony potassium tartrate (tartar emetic)

7 Lymphogranuloma Venereum—Lymphogranuloma venereum varies greatly in its manifestations It may produce only local enlarged lymphatic nodules or may in its greatest reaction cause complete obstruction of the pelvic sigmoid and even extensive ul-

ceration of the pelvis involving the rectum, vagina and urinary tract. This latter situation may terminate in a necrotic cloacal like crater. Perhaps the conditions heretofore called *esthiomene* and also probably occasionally *rodent ulcer* may be due to this destructive state. Medical treatment is indicated. Surgical correction is not directed at the local site but may be necessary to relieve intestinal obstruction or after the destruction has run its course to restore functional control. At a much later date after partial involution the colostomy wound may be closed.

8 Tuberculosis—Tuberculosis is less common today probably because of the better care and better hygienic measures available for persons with active infections. A local lesion on the vulva may be the result of blood stream dissemination or may be due to extension from the pelvic process. These lesions are usually irregular and may be quite destructive in these instances being painful. The slower growing lesions may be more hypertrophic. Occasionally a woman whose husband has pulmonary or urinary tract tuberculosis will have a tuberculous lesion on the vulva. Areas of suppuration may require drainage. Caution may be needed lest the abscess become dissecting.

9 Pyogenic Infections—Occasionally considerable edema, induration and general enlargement of a portion or all of the vulva result from pyogenic infection. These bacterial organisms may be the result of a primary urinary tract infection or may come from a primary lesion of the vulva. Should actual suppuration occur drainage is indicated. In the event that actual suppuration has not occurred sulfonamides may be very helpful either in ointment form or orally. The urinary tract and other focal sites of infection must be cleared.

Bartholin's abscess is moderately common and may be caused by the gonococcus, staphylococcus or any other organism which may be associated with suppuration. Bartholin's abscess like any other abscess should be drained when there is definite suppuration. The area is swollen, enlarged and red, dened giving the typical picture of an acute inflammatory process. This condition must be differentiated from Bartholin's cyst or other non-inflammatory lesions which irri-

tate the skin. The incision should be made on the mucous membrane and should be adequate. Occasionally not all of the secretory cells will be completely destroyed by the infection and if a sinus forms between the glands and the surface mucoid secretion from the gland should empty upon a mucous membrane which is normally moist. Drainage out on to a skin reasonably dry will become a source of irritation. The abscess will not transmit light, is not tympanic and does not show evidence of enlargement on straining.

10 Mycoses—*Actinomyces* and *blastomycosis* are rare conditions of the female pelvic organs. Adequate surgical drainage may be necessary but surgical removal is frequently impossible. Occasionally, x-ray therapy and adequate sulfonamide therapy may be of some therapeutic value.

Moniliasis is a most frequent condition in pregnancy and occasionally in uncontrolled diabetes. The infection is superficial. It occurs because of an increased amount of available carbohydrate material when these fungi are present. The organism may be carried without symptoms or tissue reaction until a proper nutritive state occurs. The production of a glycogen like vaginal epithelium in the postmenopausal period by means of estrogens may result in frank vaginal moniliasis. The vulva may be infected secondarily and may be hyperemic and moderately swollen. If the patient yields to the impulse to scratch and usually the pruritus is most severe there may be many areas of desquamation. The lesions may have a great similarity to those of atrophic vulvitis or kraurosis. The therapy is entirely medical for the diabetic patient and local fungicidal therapy is indicated for the diabetic as well as the pregnant patient. X-ray or surgical therapy is positively contraindicated.

11 Hypertrophic Anomalies of the Vulva—Hypertrophic anomalies of the clitoris are not so uncommon and misinterpretation of an enlarged clitoris may lead to great confusion about the sex of the child and its development. It may be necessary to amputate or remove a prominent clitoris in an older child or adult either to establish a normal psychologic behavior or to remove barriers for normal married life. Enlarged or pendulous labia likewise may be disturbing

and annoying. Under special circumstances it may be necessary to remove these pendulous portions of tissue. The labium is a vascular structure and its removal may be associated with severe blood loss.

ATROPHIC STATES

1 Atrophic Vulvitis (Leukoplakic Vulvitis, Kraurosis)—Pruritis is the one common persistent and unrelenting symptom. Adair Davis and Schultze made a careful study and have pointed out the three stages in the development of this condition. The first stage is one of inflammatory enlargement, edema, infection and pruritis. Abrasions and petechiae are not uncommon. The second stage is followed by involution or atrophy and beginning induration and thickening of the epidermis. There begins to be more of a mottled gray color. The third stage arrives when the skin has become inelastic, smooth, thin and parchment like. Leukoplakic areas may develop at this time or earlier and the vulvar area as a whole may not be uniform in the same state. Since kraurosis is a condition which is followed in many instances by carcinoma, the commonly accepted treatment is vulvectomy, all of the altered pathologic tissue being removed. This may mean removing the mucosal urea down to the hymenal ring and far laterally. When the skin lesions encircle the anus it is desirable to leave a strip on either side in which to anchor the rectum and at a later date when the first incisions have healed to remove the remaining tissue. The condition may recur. X-ray therapy has received some endorsement but since it does not prevent the development of cancer subsequently it is not recommended. Moreover it does not always cure the primary condition. Injections of alcohol and other medications under the diseased tissue or to the nerve supplying these areas seem only to eliminate the symptoms and not attack the disease. Various ointments and other medications have been recommended but do not always produce a cure. Hesseltine used large doses of members of the B complex and found improvement in a fair percentage of cases. It is possible that part of the conditions which heretofore have been recognized as kraurosis may actually be manifestations of vitamin deficiency. Until a sufficient num-

ber of tests and studies have been made upon patients with these lesions this question must remain controversial. Anyone attempting to use large doses of the B complex, ascorbic acid and perhaps other vitamins should be prepared to follow the patient sufficiently long to make sure that an absolute cure ensues or to institute appropriate surgical therapy lest a malignant growth develop. Skin changes in vitamin deficiency, particularly in pellagra, riboflavinosis and thiamine deficiency may be associated with changes similar to those in kraurosis. Tausig urges vulvectomy but warns against tightness and stenosis of the introitus (Fig 703).

Fig. 703—Operation for leukoplakic vulvitis. A vulval flap and double anastomotic technique showing extent of denudation in an advanced case. (Tausig)

2 Phimosis—Phimosis is rarely of importance in the female. Occasionally there may be redundant prepuce and constriction over the clitoris so that normal cleanliness and hygienic measures cannot be maintained. Occasionally and particularly in obese persons a low grade inflammatory process may become established under the preputial fold. Incision or circumcision is usually sufficient. Occasionally when the infection is quite chronic and persistent it may be necessary to amputate the clitoris near the bifurcation of the corpus spongiosum.

3 Atrophic Anomalies of the Vulva—Atrophic anomalies of the vulva are likely to be the result of arrested development and accordingly will present little opportunity for correction or stimulation through hormonal or other therapy in adults. There is little chance of improvement by surgical means except by plastic reconstruction. This applies particularly if there is a small introitus in which case perineotomy or introital dilation alone may suffice. To correct dyspareunia due to a small introitus the lubricated vagina may be dilated and a midline incision made of sufficient degree. Occasionally a single or even a double mesolateral incision may be justified. After adequate room is obtained the vaginal mucosa is brought down to the skin so that the introital incision is closed transversely.

BENIGN NEOPLASMS

1 Bartholin's Cyst—Bartholin's cyst results because of occlusion of the duct from Bartholin's gland. Infection or injury is the likely cause for occlusion. Small or asymptomatic cysts are not sufficiently important as a rule to require surgical attention. Any cyst which produces symptoms or which is large enough to interfere with locomotion, coitus or delivery should be removed. A Bartholin's cyst transmits light. Even though it may dissect upward into the labium majus it is concrete and sharply defined. It is dull on percussion and does not have an impulse with sudden strain. It can be aspirated and filled with a solidifying oil or fat such as paraffin which would melt at about 40 to 42° C. Most surgeons prefer merely to incise the skin and enucleate the cyst without making a mold of the cavity. The incision may be made either on the normal epidermal area or in the mucous membrane. It is recommended in most instances that the incision be made on the mucous membrane over the length of the cyst proper and that blunt dissection be used to free the cyst from the adjacent tissue. Bleeding points and vessels will be found near the depths of the cavity, and after the cyst has been freed to this site, hemostats should be placed along the pedicle like area. This will allow for detachment of the cyst and will also prevent the vessels from retracting. After bleeding points are properly controlled the cavity is closed with

interrupted buried catgut sutures, probably chromic No. 1 will be preferable. The skin area can be closed either with fine catgut or with a nonabsorbable suture such as cotton or silk. It is important in the event that the cyst is opened that the complete cyst wall be removed; otherwise there is great likelihood of recurrence.

2 Hydradenoma—Hydradenoma is a tumor arising from the sweat glands. Usually it is of moderate to small size but may be disturbing to patients. When sufficient symptoms are present removal is indicated.

3 Fibroma and Lipoma—Fibroma and lipoma of the vulva are tumors arising from the respective mesodermal tissues. Surgical treatment is indicated when they produce symptoms. These tumors will not transmit light and can be differentiated from varicosities since they cannot be reduced in size and do not give an impulse on sudden strain but they have the consistency of the usual fibroma or lipoma.

4 Mammary Tissue—Aberrant or accessory mammary tissue may be found near the mons veneris. We removed from one patient two masses of tissue, one on each side of the clitoris, which microscopically proved to be mammary tissue. The patient had noted changes in these two masses like those of the normal breasts. It may be necessary in removing such mammary tissue to remove the clitoris but ordinarily this is unnecessary. A biopsy might be taken but usually these small sites are better managed by complete removal for the process might be malignant. If a biopsy is taken and mammary tissue is found removal is advised. X-ray treatment should not be used more over it might interfere with the normal sensory nerves to the vulva and possibly contribute to loss of libido.

5 Endometriosis—In infrequent instances endometrial tissue has been found in the inguinal canal which may descend down to the labia majora. Endometriosis on the other hand may be one or another means arrive on the vulva and present the picture of a dark violaceous growth. Biopsy would reveal the typical pattern of endometriosis. Endometriosis if it is diffuse and general and elsewhere about the pelvis may need to be treated by castration. Local processes can be individually treated. Castration may

be accomplished by bilateral oophorectomy or by deep x-ray therapy. The clinical situation should dictate the type of treatment (See section on Endometriosis).

6 Cysts of the Canal of Nuck—Cysts of the canal of Nuck are quite rare. They may be unilateral or bilateral and may be multiple but are not necessarily so. Treatment consists of extirpation. They may be found in the inguinal canal, mons veneris or even the labia but usually are above the level of the mons veneris.

MALIGNANT NEOPLASMS

1 Carcinoma—Primary carcinoma of the vulva may arise either from the epithelium of the vulva or from the glands of the epidermis. Taussig claims the average age is 60 and that approximately 4 per cent of all gynecologic cancers arise from the vulva. The growth may arise also from the glands of the clitoris. There are occasional reports of carcinoma of Bartholin's gland. Carcinoma has been a frequent successor to kraurosis or atrophic vulvitis. Details of the histopathologic descriptions of vulvar malignant growths may be found in standard text books and in the current gynecologic literature. Taussig has made an extensive study of this subject. It is generally conceded that deep x-ray and radium treatment are unsatisfactory from a therapeutic viewpoint. Surgical removal of the vulva is indicated, according to Taussig and others. The malignant tissue must all be completely removed. If the lesion is at all advanced the chance of complete removal is only slight. As metastasis occurs quite early, Taussig recommends removal of the inguinal and femoral glands either at the same time as radical vulvectomy or as a second stage operation. He advocates his modification of the Basset technique. Taussig says:

In the technique of operation it must be borne in mind that the complete operation consisting of bilateral removal of the lymph glands and complete vulvectomy is a procedure that requires about two hours time and should therefore not be employed as a one-stage measure except in a relatively early case with the patient in good physical condition. A two-stage removal is preferable: the second operation following about two or three weeks after the first. If the ulcerative process in the vulva is advanced vulvectomy should be accomplished first and gland removal later. In earlier cases this procedure may be reversed. In very old women who are poor operative risks one must

at times be satisfied with a simple vulvectomy. Local anesthesia preceded by twilight sleep is satisfactory and does not materially interfere with wound healing. The operative mortality is about 5 per cent.

The writer's modification of Basset's original technique consists of an incision 6 inches long extending from a point 1 inch internal to the anterior superior spine down over Scarpa's triangle. The entire inguinal canal is then opened up from the external to the internal ring and the internal oblique muscle pulled upward exposing the deep epigastric vessels at their point of origin from the external iliac vessels. After these vessels have been doubly ligated and cut the space on either side of the external iliac vessels is opened up and the lymph glands in this area are separately removed. Then the entire chain of superficial inguinal and femoral lymphatics including the tissue of Scarpa's triangle is freed and lifted up. The saphenous vein is cut and ligated close to the femoral and if necessary Poupert's ligament is cut over the femoral ring to permit the more complete removal of the lymph gland of Cloquet situated just above the ring. Closure of the inguinal canal and the wound is accomplished in the usual manner with a drain through a separate stab wound over Scarpa's triangle.

	Number Percentage	
	Cases	Survival
Basset and vulvectomy	41	24
Superficial or incomplete gland removal and vulvectomy	21	0
Vulvectomy only	12	1
Radiation treatment	21	1
Palliative measures (no excision or radiation)	6	0
Total	101	26

A malignant growth arising from the clitoris may be more extensive and may spread more rapidly than the usual basal epidermal growth. A malignant growth arising from the glands likewise may spread more rapidly. A malignant growth from the urethra may extend out on to the vulva obscuring the primary site. The use of x-ray treatment subsequent to surgical removal has been recommended by some.

2 Sarcoma—Sarcoma of the vulva is quite rare but theoretically could develop just as it does in any other site of the body. Its treatment must be individually considered.

3 Metastatic Lesions—The presence of metastatic lesions inheres the advanced growth of a primary tumor. Surgical removal of metastatic lesions should be done only for symptomatic relief, certainly not as a curative process. Radium may be used on metastatic lesions depending upon their

site and the type of malignant growth. These lesions may result from implants or metastasis from carcinoma of the cervix or uterus or other organs or rarely from malignant hemangioma.

Chorioepithelioma involving the vulva indicates a metastatic lesion. Therapy should be directed principally toward the primary site which would be almost always the uterus. Surgical removal or adequate x-ray therapy to the uterus and also to the local lesion should offer the best prognosis. Removal of the uterus is advised by most obstetricians and gynecologists.

4 **Malignant Melanoma**—This condition is of rare occurrence.

MISCELLANEOUS CONDITIONS

1 **Varicosities**—Varicosities of the vulva are moderately common. They are associated frequently with vaginal varicosities and usually occur in women who have varicosities of the legs and rectum. The labia majora are normally vascular but become more vascular as varicosities develop. The surface is irregular owing to the distention of the veins. Women tend to have a sense of tiredness or heaviness if they are on their feet a great deal because of the stasis and distention. The pregnant state and pelvic tumors or masses accentuate varicosities and increase the amount of venous involvement. Ordinarily varicosities of the vulva do not need surgical attention. In the event that their size and condition justify surgical intervention ligation of the individual vessels in a very vascular area is carried out. Severe blood loss can occur during surgical procedures upon the vulva.

2 **Hematoma**—Hematoma of the vulva may occur as the result of trauma during delivery or resulting from a fall upon an object or from an automobile or bicycle accident. The broken blood vessel should be isolated and ligated, the clot evacuated and the wound closed tightly. If the hematoma is old and uncomplicated one may observe the state for several days. An uninfected clot will be absorbed. If the hematoma is infected adequate incision and drainage is indicated.

3 **Wounds**—Wounds of the vulva are uncommon but do occur. The nature of the injury will determine the procedure at the

time. Women in combat zone areas may suffer vulvar injury from explosives. If the wound is relatively clean the control of bleeding, debridement and closure may be sufficient. If the wound is badly contaminated it may be advisable to approximate the edges but allow for drainage after the control of bleeding and the debridement have been completed. The use of tetanus antitoxin must be given consideration in each instance of injury depending upon the cause of injury and other factors. Individuals injured on the bridge path or in the riding stable or around gunfire or ammunition should receive tetanus antitoxin. Sulfanilamide or one of the other sulfonamides may be placed in the wound. Cultures should be taken at the time of the initial treatment to insure appropriate therapy in the event that an infection becomes active.

4 **Pruritus**—Irritation of the vulva is fairly frequent in association with urethral and bladder lesions and occasionally in association with cervicitis or vaginitis. The treatment should be directed at the principal cause using only sufficient local therapy for symptomatic relief. Surgical treatment is contraindicated. Certain urethral lesions or bladder conditions may cause severe pruritus. Occasionally, if there is poor anal hygiene or an injured anal sphincter vulvitis may develop secondarily.

5 **Fistulas**—Fistulas of several types may involve the vulva. Therapy should be directed at eradication of the fistulous tract. It may be necessary if it connects with the rectum near the sphincter to lay the sinus open completely allowing the wound to heal by granulation. If the fistula connects only with the vagina it may not require attention.

CONGENITAL MALFORMATIONS OF THE VAGINA, UTERUS, OVARIES AND TUBES

In general the abnormalities of development of the ovaries are due to interference with the development of the genital ridge and its surrounding epithelium and non-descent to lack of the proper position of the guberniculum. Malformations of the vagina, cervix and tubes may be due to improper canalization of the müllerian ducts or improper fusion of the distal ends of the ducts in the region of the urogenital mass or lack of absorption of septa after fusion. Lack of proper alignment of the tubal portions of the ducts will prevent proper development of the fundus and body of the uterus.

The Vagina—Congenital malformations of the vagina are due to non union or incomplete fusion of the müllerian ducts or to lack of removal or incomplete removal of the septa after they have been united.

Absence of the vagina is due to the failure of the fused ducts to canalize and atresia is due to improper canalization of the ducts. With absence or atresia of the vagina the uterus is usually functionless and hematometra is rare. Secondary sex characteristics are usually properly developed and the desire for marriage is normal. In such cases reconstruction of the vagina may be necessary.

Double vagina occurs because the septum formed by the fusion of the two ducts has not been absorbed. The septum may extend as far as the hymen and to the vaginal fornix. It divides the vagina into two equal or unequal parts and two cervixes are always present. Removal of the septum is not difficult and may be performed in order to enlarge the orifice to aid conception or to avoid tears at delivery. A double uterus nearly always occurs when there is a double vagina and cervix. Atresia of one half of a double vagina is possible and unilateral

hematocolpos, hematosalpinx and hematometra are not unknown. Transverse septa do occur but are not usual.

Imperforate hymen is due to a lack of breaking down of the septum which shuts the uterovaginal canal off from the urogenital sinus or to a growth of a new diaphragm. This defect may result in an accumulation of mucus behind the septum in the infant or very young child and later after menstruation has commenced hematocolpos, hematometra and hematosalpinx. The treatment is incision of the hymen with perfect asepsis as infection occurs easily. When the hymen is imperforate and the internal genitals are small there may be no vagina.

The *clitoris* arises from the genital tubercle near the urogenital orifice and is analogous to the penis. Hypertrophy is noted as a masculine characteristic of pseudohermaphrodites. Hypertrophy is also present as an evidence of masculinization in adrenal cortex overactivity and in the presence of an ovotestis, testicular tubular adenoma of Pick or arrhenoblastoma of the ovary. Absence of the clitoris is rare.

Hypospadias is a lack of closure of the posterior wall of the urethra caused by lack of development of the urethrovaginal septum.

Epi-spadias is due to the defective formation of the anterior wall of the urethra and may be accompanied by separation of the pubic bones and lack of closure of part of the anterior abdominal and bladder walls (exstrophy).

The Uterus—Congenital abnormalities of the uterus are due to complete or partial failure of fusion of the two müllerian ducts or to lack of development of the tissue (mesenchyme) about the two uterine ends of the early fallopian tubes above the cranial end of the uterovaginal canal. Complete absence of the uterus is not found except in extreme maldevelopment of the embryo for even when the vagina is absent, a small rudimentary cord of uterine tissue can be found. A third uterus is possible but extremely rare. One such case has been reported.

More common uterine abnormalities are the following:

1. **Uterus didelphys**—double uterus, double cervix and double vagina. This is

rare and most often noted in a non viable monster. It is due to failure of fusion of the mullerian ducts.

2 Uterus duplex bicornis—double uterus with joined cervixes but separate canals and double or single vagina. This type is not uncommon and is due to complete or partial failure of union of the mullerian ducts.

3 Uterus bicornis unicollis—double uterus with single cervix and vagina. It is due to partial fusion of the mullerian ducts or to lack of proper alignment of the tubal portions of the ducts in the region of development of the body and fundus.

4 Uterus arcuatus—a slight depression in the exterior of the fundus which is due to lack of proper development of the body and fundus around the uterine ends of the tubes and upper end of the uterovaginal canal.

5 Uterus bicornis septus—normal appearing uterus or with a slightly depressed fundus but with a septum from fundus to external os. It is due to lack of absorption of the uterine and cervical septa. The vagina is single.

6 Uterus septus duplex cum vagina septa—a uterus with an anteroposterior septum and a vagina divided by a septum. This is due to lack of absorption of the septa.

7 Uterus biforus—normal uterus with a double cervical orifice. This is due to lack of absorption of the cervical septum.

8 Uterus unicornis—one half of a normal uterus. This is due to absence or aplasia of one mullerian duct.

9 Uterus bicornis cum rudimento cornu alterius—nearly normal uterus with a rudimentary horn. This is the deformity of the most practical importance. At the extremity of the rudimentary horn the fallopian tube and round ligament are attached. The cavity of the horn may be complete or partial. Infection or pregnancy is possible in the rudimentary horn. Diagnosis may be difficult.

These nine types are the most important developmental abnormalities. No treatment is necessary until some difficulty arises as both uteri or only one may function properly. Pregnancy can take place in either but activity is usually greater on one side. Atresia of one vagina or one cervix may cause difficulty and various diagnostic possibilities must be considered. The extra

uterus or the rudimentary horn can be removed but a developmental defect is not *per se* an indication for operation.

The Ovary—Bilateral absence of the ovaries is extremely rare and probably occurs only in non viable monsters. Unilateral absence of the ovary may take place when one mullerian duct is absent. There must also be absence of the tube and the uterus should be unicorn. It is conceivable that in fetal life one ovary might be twisted off. Supernumerary ovaries are occasionally seen and are usually near the normal ovarian site or are found on the posterior abdominal wall. A third ovary is a rarity. A tube or utero-ovarian ligament must be present. A third or supernumerary ovary probably explains the occurrence of menstruation or of pregnancy after bilateral oophorectomy. An ovary is not uncommonly found in the inguinal canal during an operation for hernia.

Ovotestis a combination of ovary and testicle is very rare and is a form of masculinization.

The Tube—Bilateral absence of the tubes is chiefly found in non viable monsters. Unilateral absence of the tube may occur with absence of one ovary and is due to absence or aplasia of one mullerian duct. Accessory tubes are not uncommon and occur as double ostia or as diverticula of the side of the tubal wall. Extrauterine pregnancy may occur in these tubes. Third tubes are rare and are seen in association with true third ovaries. Unilateral defects such as atresia can occur as a result of tick of canalization of the mullerian duct.

URETHRAL CARUNCLE

Definition—Urethral caruncle, occasionally known as irritable caruncle or urethral angioma, is a true benign neoplasm. It may be the size of a pinhead or of the little finger and is usually found at the external orifice of the urethra on the posterior wall usually in the lower third. It may be sessile or pedunculated with a small or broad base and a thin or thick pedicle. It is usually a dusky dark red but occasionally bright red. It is usually single but may be multiple and is seen most frequently about the menopause.

Etiology—The etiology is not clear but parturitional trauma and infection or gonorrhea and inflammation of Skene's glands may be considered.

Pathology—According to Frank there are three types of caruncles—the granulomatous, the papillary angiomatous and the telangiectatic or blood vessel type.

Symptomatology—Interference with the function of the urethra may cause great distress. Dysuria and frequency are very common and hematuria, urinary retention and incontinence occur. The patient may be distressed and anxious and often a severe neurosis develops. Dyspareunia and bleeding add to the discomfort of the patient. The symptoms may last for from ten to twenty years and many unsuccessful attempts may have been made to treat the condition.

Diagnosis—Protrusion of the urethra is frequently confused with caruncle and it is sometimes difficult to distinguish between them. Varicosities of the urethra, polyp of the urethra, condyloma, cysts of Skene's glands, myoma, fibromyoma, sarcoma and carcinoma as well as adenoma and nevus both pigmented and non pigmented must be differentiated. The caruncle is not always visible; a small hair pin speculum may be necessary to visualize the upper part of the lower urethra. Cystitis may clear up after removal of the hidden caruncle.

Prognosis—Complete excision is the only cure and as this is extremely difficult the prognosis is not good. The tumor infiltrates and recurs easily. Malignant changes are rare but have been known to occur.

Treatment—Radical excision is best. DeMeigs suggests circumcision of the urethra

with suture of the urethral mucous membrane to the vaginal mucous membrane. Deep coagulation with the endotherm reported if necessary is an excellent method. Simple excision is rarely sufficient. The actual cautery or silver nitrate usually fails. Radium occasionally gives a good result but is not advised.

VAGINAL FISTULA

VESICOVAGINAL FISTULA

Vesicovaginal fistula is a surgical entity that has developed as a complication subsequent to surgical procedures on the pelvic structures, difficult and complicated deliveries, radiation therapy for carcinoma of the cervix or accidental trauma. The greatest number of these fistulas in more recent years fall in the first group but there have been some from each group. The surgical problems involved in the treatment of vesicovaginal fistula require considerable thought, complete urologic investigation and a working knowledge of the various surgical procedures that are known and that have proved to give the best results for different types of fistula. There is not just one operation or one method of approach that is applicable to all vesicovaginal fistulas. The number of fistulas secondary to surgical procedures on the pelvic structures and vaginal plastic operations is definitely greater than in previous years. Vesicovaginal fistulas are rarely produced by granulomatous disease.

Diagnosis—The diagnosis of a urinary fistula is usually evident from the leakage of urine, excoriation of the labia, inflammation

tion of the vagina and the odor but to locate a small fistula may be extremely difficult. Accurate information as to how the fistula occurred in the first place is most important. A large opening can be easily seen and felt by the examining finger. A fistula 1 or 2 mm. or less in diameter may have to be visualized by placing a colored solution in the bladder and noting its point of exit. However, accuracy in the location of the fistula or fistulas is so important that very careful cystoscopic examination is a prerequisite to the successful repair of the fistula. A fistula situated near the urethral sphincter or near the ureteral meatus is more difficult to handle surgically than one situated elsewhere in the bladder.

Any complications involving the upper part of the urinary tract must be excluded. A fistula may involve a ureter and may be followed by hydronephrosis or a functionless kidney on the involved side. A fistula situated high on either side of the vaginal vault may be a ureterovaginal fistula instead of a vesicovaginal fistula. These facts should be determined prior to surgical treatment. At the time of cystoscopic examination the extent of any inflammation of the vesical mucosa can be determined and appropriate measures taken to eliminate it before surgical treatment is instituted.

Treatment.—There is much that can be said regarding the treatment of vesicovaginal fistulas but briefly there are certain conditions which are a prerequisite to successful closure. No surgical procedures should be undertaken until all evidence of infection of the bladder and any complicating condition of the upper part of the urinary tract have been eliminated. Spontaneous closure of a small fistula such as follows delivery is fairly common. It also is true that a small fistula that occurs high in the dome of the bladder following a surgical procedure has been observed to close spontaneously if the bladder is kept continuously empty by a retaining catheter for a few days. If such a fistula does not close early it will be useless to continue conservative management. Light cauterization of a small fistula or electrocoagulation of a pinpoint fistula may result in closure. This type of treatment should be limited to small fistulas of the recurring type.

Most fistulas make their appearance a few days subsequent to operation as a direct result of necrosis. In inflamed tissue immediate surgical repair is likely to result in a high incidence of failures; therefore it is advisable to postpone surgical repair for six weeks to three months in order that all edema and other evidence of inflammation may subside completely. Failure to observe this rule is one of the greatest causes of recurrence of the fistula. Furthermore if recurrence follows what seems to be an excellent closure it is best not to touch the fistula again for several weeks.

These fistulas may be repaired by the vaginal route or by the transvesical route. The vaginal approach carries less risk and offers a greater chance of success than any other approach. Accurate exposure can best be had with the patient in the Mueske position especially in cases in which the fistula occurs after total abdominal hysterectomy. All scar tissue around the fistula should be excised completely. This is best accomplished by incising the vaginal wall adequately behind and in front of the fistula. The incision should surround the opening of the fistula and sufficient scar should be left attached to the fistula to pull the scar upward into the vagina. The vaginal wall is dissected away from the bladder for 1.5 cm. on each side of the fistula. When the scar is excised from the fistula it will always be much larger than it originally seemed to be. The fistula is then closed with three rows of catgut sutures in the bladder wall. Each row is continuous; the first one consists of no. 000 chromic catgut and just approximates the mucous membrane of the bladder without a suture passing through it. The second row of sutures consists of no. 00 chromic catgut; it begins 1 cm. beyond the original row of sutures and extends 1 cm. beyond where the previous one ended. The third row of sutures is placed in the wall of the bladder and consists of no. 0 chromic catgut. It begins 1 cm. beyond the second row of sutures and ends 1 cm. beyond the end of the second row. There must be no dead space between any of the suture lines. In other words the anastomosis should be done exactly as an intestinal anastomosis. Purse-string sutures should not be employed. I would not advise the use of non-

absorbable sutures in the vesical wall. The vaginal wall should be closed with interrupted sutures preferably of cotton or silk. Each suture should incorporate some of the vesical wall so as to hold the vaginal wall and vesical wall firmly together. All bleeding should be completely controlled.

Postoperative Care—The best results are obtained by keeping the patient on a Bradford frame although this is not compulsory. An indwelling straight catheter should be kept in place from ten to fourteen days and the vesical urine should be kept slightly acid by the administration of small doses of ammonium mandelate. Any vaginal examination should be absolutely prohibited for at least three weeks. Only hernia can result from placing a speculum in the vagina during the period of healing. The non-absorbable sutures should be removed in four to six weeks.

RECTOVAGINAL FISTULA

There are five types of rectovaginal fistula, namely, (1) that which develops subsequent to repair of complete laceration of the perineum (2) that which occurs simultaneously with vesicovaginal fistula (3) that which arises insidiously and in conjunction with an abscess in an anal crypt (4) that due to direct violence or an ill fitting pessary and (5) that which arises from granulomatous disease or malignant disease.

Diagnosis—Escape of gas and feces into the vagina is usually diagnostic of a communication between these two cavities. It is caused either by trauma or by disease.

Treatment—An inguinal colostomy as a preliminary procedure in a case of large rectovaginal fistula particularly when the fistula is situated high in the rectovaginal septum may be a distinct advantage. Also it should be considered in cases in which repeated operations have been performed to close the fistula. In cases in which the fistula is tuberculous syphilitic or due to an ulcerating carcinoma a permanent colostomy is probably the only procedure advisable. Unlike a vesicovaginal fistula a rectovaginal fistula rarely heals spontaneously and seldom can be closed successfully by coagulation or enterization.

The cause of failure in the treatment of rectovaginal fistulas is due to infection the

lack of blood supply and tension. A small fistula that occurs with an intact perineum and anal sphincter is probably the most difficult to treat satisfactorily; the closer the fistula is to the perineal body the greater the hazard of recurrence. In these cases the anal sphincter should be kept constantly dilated for the escape of gas and feces for from ten days to two weeks.

Rectovaginal fistula incidental to incomplete healing of complete perineal laceration should be treated by complete division of the scar or the remaining portion of the perineum. The scar in the margin of the rectal wall should be excised completely. The anterior wall of the rectum should then be repaired in layers as far outward as its normal junction with the anus and sphincter muscles. The ends of the sphincter muscles should never be isolated from the scar but the scarred ends should be utilized to pull the sphincters together. The perineum is then repaired by the usual technique.

Failure to close a fistula of this type is usually due to pulling the rectal wall forward to meet the sphincters rather than repairing the anterior rectal wall in layers.

The most troublesome fistula is that which occurs after infection in an anal crypt. This type of fistula is rare nevertheless it does occur spontaneously and must be recognized. The cause of this type of fistula is the same as that of fistula in ano. Repair will never be successful until all evidence of infection from the anal crypt has been eliminated; therefore the fundamental principle in treatment is complete division of the fistulous tract including complete division of the sphincters and perineal body if necessary. After all infection has been eliminated and healing of the sinus tract is complete the perineum, anal sphincters and rectal wall should be repaired. Failure to observe these principles will invariably result in failure.

Enemas should not be given for ten days to two weeks after operation. Then only an oil retention enema should be given and retained overnight. The patient should be urged to evacuate the bowel without repeated enemas. Mineral oil given to maintain a soft stool is one of the most potent causes for recurrence of the fistula. An empty rectum or a dry stool in the rectum is most favorable.

VIRGIL S. COUNSELLER

XXXVI. PLASTIC SURGERY

GENERAL PRINCIPLES

Plastic surgery deals with the repair of congenital or acquired deformities for the improvement of appearance or function and occasionally for the relief of pain. This repair is usually accomplished by means of an adjustment of tissues with or without the use of adjacent or of distant transplanted tissue. Plastic surgery overlaps general surgery and all the various special branches of surgery. Mechanical appliances or prostheses may be employed either alone or in conjunction with it.

Congenital malformations arise from embryonic maldevelopment or intrauterine disease such as syphilis. After birth deformities are required as a result of disease or trauma or a combination of the two. The trauma may be accidental or intentional as from surgical operations.

Usually the tissues involved are on the external surfaces of the body but deeper tissues also may be affected. The degree of deformity depends on the location as well as the extent of the lesion.

A thorough knowledge of the tissues involved and of the principles of wound healing are required of the surgeon and he must know the operations that have been evolved and be able to adapt them or to devise special procedures to fit particular circumstances. It is important to diagnose where misplaced tissues originally belonged or what alterations from the normal have occurred and also to determine what must be done to correct these conditions.

As there is a choice of procedures which can be used in the repair of any deformity the surgeon should suit the method to the individual case taking into consideration the costliness, the length of time available and the patient's temperament, age and physical condition. All of the factors should be weighed and advice should be given against an operation that offers a considerable chance either of not succeeding or of adding undue deformity. It is often easier to satisfy a patient who has a marked de-

formity than one with nearly perfect features.

Plastic operations should never be performed in the presence of infection except when absolutely necessary; provision should then be made to combat it by adequate measures. As most plastic procedures are elective conditions for operation should be as nearly ideal as possible; not only should the general health of the patient be satisfactory but local suppurative processes such as acne, pustules, boils, etc., should be absent. Infection may detract considerably from an otherwise satisfactory final result and may even cause complete failure.

In cases of emergency, various conditions such as infection, fracture, subdural hemorrhage, shock, etc., may frequently demand treatment before any plastic procedure can be carried out. If possible the plastic surgeon should perform the first emergency repair since the secondary repair of deformities may be rendered more difficult because of improper repair at the first operation.

In general transplanted tissue should resemble the tissue it replaces as closely as possible. On the face the skin varies in thickness, color, texture, hairiness and tension. All of these factors should be considered in selecting the donor tissue.

Plastic surgery is a type of sculpture in which living tissues are used. These tissues require nourishment or they will die. A satisfactory blood supply—venous as well as arterial—must be maintained to the part. Frequently an otherwise well performed procedure may fail because of disregard for the proper amount of pressure maintained in the dressings so as to prevent passive congestion. Pressure also aids in controlling hemorrhage and in approximating raw surfaces.

Careful hemostasis, use of the finest needles and suture material and gentle handling of tissues are essential for the best results. Buried sutures take the burden of tension from the skin sutures and allow the early removal of the latter so that they leave no scars. Constriction of the skin by sutures causes necrosis and necrosis means scarring.

and deformity. The more loosely the skin sutures can be tied, in conformance with good approximation of the cut surfaces, and the earlier they are removed, the smaller will be their permanent mark on the skin.

Postoperative care, both in the dressing at operation and subsequently, is most important. These dressings, if at all complicated should be taken care of by someone capable of handling all contingencies that may arise.

Reparative processes in wounds continue for months and even years, and grafts which are not entirely satisfactory at the end of a few months may be vastly improved at the end of two or three years.

CLOSURE OF DEFECTS; TISSUE SHIFTING AND ROTATION; PEDICLE FLAPS

After excision of a scar or some other superficial pathologic lesion, the resultant defect may often be closed by bringing to-

Fig. 701—*a*, Elliptical incision which can, after undermining be closed in a straight line. This procedure is extremely useful and the long axis of the ellipse should be in the most favorable direction of skin tension. *b*, excision of a lesion with closure in the form of a Y. *c*, schematic drawing of closure of a square defect by advancing or shifting skin and subcutaneous tissue from one side. *d*, closure of defect by advancing skin and subcutaneous tissue from both sides of a square defect. *e*, closure of a large defect by rotation of the skin and subcutaneous tissue. Note the relatively large scar. *f*, closure of a defect after excising a lesion on the upper lip below the nostril. Tissue is advanced from the cheek. Simple closure would result in distortion of the lip or nose. *g*, Z incision for correction of a displaced commisure of the mouth with transposition of flaps. *h*, closure of defect by simple pedicle flap with return of pedicle to the donor bed after the flap has been severed.

gether adjacent tissues. Simple approximation of the skin edges by sutures, however, may not suffice because any excessive tension gives rise to subsequent spreading of the scar. The connective tissue trabeculae in the adjacent subcutaneous tissue—whereby the skin is attached to deeper structures—

tissue may, however, be incised upward from the depths of the undercut tissue to the skin to allow further relaxation without subsequent visible scarring of the skin.

An elliptical skin incision encompassing the tissue to be excised with the aid of undercutting should leave an inconspicuous

The flap has been raised and a full thickness graft from the arm has been laid across the middle of the flap with the skin surface down so as to form a lining of the new nose according to Nen's technique. The flap was later raised and the distal end was folded on itself to form the columella and the two alae and was sutured to the full thickness graft. It was then rotated downward to form the new nose. The major portion of the defect of the forehead was covered with a full thickness graft. *e* end result. The flap has been severed and the pedicle returned to its former bed. The full thickness skin graft to the forehead is seen. A cartilage graft from the rib has been inserted to build up the bridge and two cartilage grafts have been inserted to maintain the normal shape of the columella and alae. *f* end result, profile view.

may be severed by undercutting and thus provided a sufficient blood supply to the skin is maintained, will permit stretching of the skin and relief of tension so as to allow closure with sutures. No relaxing incisions through the skin at a distance from the wound should be required after sufficient undercutting, the undermined subcutaneous

linear scar if closed in the most favorable direction of skin tension (Fig. 704 *a*). The method of excising small lesions is one of the most useful and satisfactory procedures because it is the simplest and produces a minimum of deformity.

Although many complicated closures of defects have been devised and may be used

ig 704 a to g) the simpler the method
ploved the better Incisions radiating

a *pedicle skin flap* The transplanted flap eventually receives sufficient nourishment from its new bed to be independent of the pedicle. The flap may then be severed from the pedicle and shaped to fit the defect and the pedicle may be excised or returned to its original donor bed. It is evident that at least two operations are required for repairing a defect with the ordinary pedicle skin flap.

After a flap has formed its new attachment there may be enough blood supply by a reversed flow to nourish the entire pedicle when severed at its base. The freshly severed base or the entire pedicle may then be attached to another defect. When the two ends are used alternately as points of attachment

portion may be sutured back in its bed and subsequently shifted. This is termed a *delayed flap*.

To avoid the usual infection of the raw surface of the simple pedicle flap and also to increase the vascularization Gillies³ devised the *tubed pedicle flap*. At the first operation a closed tubed pedicle is formed similar to a suitcase handle by undermining between parallel incisions and suturing the inner skin edges together with the surface skin outside. The lateral skin edges are approximated after undercutting or the bed is grafted so that no raw surface is left exposed to bacterial invasion. A flap at one end of this tubed pedicle with or without further de-

Fig. 79—Schematic diagram of tubed flap from scalp to forehead (repair of forehead flap) (flap B artery and vein C tunnel made in the skin to permit translocation of flap D bed prepared to receive flap) 1 Flap placed (flap B) flap in new position 2 Hair-bearing skin takes the place of absent eyebrow B new location of vessel in pedicle tunnel

so as to advance the pedicle flap by stages to a defect in another part of the body this is termed a *caterpillar* or *jumpy flap*. By making the intermediate attachment to an area a great distance may be quickly covered by a comparatively short caterpillar pedicle flap.

In order to increase the vascular system in a pedicle flap before transferring it and so to insure against necrosis a portion of the flap or pedicle may be raised from its bed at a preliminary operation and subsequently after about ten days the entire pedicle flap may be raised and shifted. At the preliminary operation the underlying tissues may be kept apart by introducing a thin membrane or preferably to avoid infection the raised

living can then be shifted more safely and more aseptically than can the simple pedicle flap. If a site is selected which embodies large vessels in the tube such as the thoraco-epigastric vessels the blood supply is better assured and long tube may be made without necrosis especially if a central skin attachment is temporarily retained.

The so-called *island flap*⁶ consists of skin and subcutaneous tissue with the pedicle comprising only the nutrient vessels and a minimum of surrounding tissue (Fig. 709). This flap is brought through a tunnel and sutured into the defect. The operation is completed in one stage. Its use is naturally limited to selected donor areas supplied with adequate blood vessels.

FREE SKIN GRAFTS

Under favorable conditions many types of tissue completely freed from the rest of the body can be successfully transplanted. Free skin grafts are particularly useful for covering certain surface defects and three main varieties are generally employed.

Small deep skin grafts erroneously called pinch grafts may be used for covering healthy granulating surfaces. The original grafts of Reverdin⁸ consisted entirely of epithelium but were not found to be as satisfactory as the small deep grafts which in addition to the epithelial layer contain nearly the entire depth of the derma. The skin is picked up with a needle and freed with a sharp scalpel or razor and the grafts from 0.6 to 0.9 cm. in diameter are transplanted to the granulations with their cen-

skin by collodion. Care must be taken not to allow the granulations between the grafts to grow above the level of the epithelium as spreading of the latter will be hindered or prevented. The judicious use of a silver nitrate stick or of curved scissors may be necessary to reduce the granulations. The healed grafted area contracts markedly and has a somewhat pebbled appearance but this becomes less conspicuous with time.

Sheets of split skin grafts (Fig. 710) may be skived free and with a long knife or razor and are usually taken from the thigh, the abdomen, the back or the arm. During the removal the patient's skin is flattened out and stretched between a stationary straight edged object such as a thin board or square enameled dish and a similar object or a Blair suction box.⁹ The latter is

Fig. 710—*a* Condition on admission twelve weeks after burn from gas stove. Note the excessively high granulations on the upper arm. *b* Condition eight months after excision of granulation tissue and transplantation of thick split skin grafts.

ters about 1 or 1.5 cm. apart care being taken in the transfer not to contaminate the donor area. The intervening granulation spaces eventually become epithelized from the graft edges. The grafted area is dressed with overlapping strips of gutta serena or adhesive tape with vaselin gauze or better still xeroform gauze* with compresses of physiologic saline solution or of a surgical solution of sodium hypochlorite which are frequently changed. The grafts may be held in place for three or four days by one layer of wide mesh gauze which is fastened to the surrounding

Many layers of narrow mesh gauze in an oblong tin are saturated with the ointment and sterilized

made to withdraw progressively from the stationary object just ahead of the advancing knife. The first grafts of this type devised by Ollier¹⁰ and Thiersch¹¹ contained only the epithelium but *thick split skin grafts*¹² containing nearly the whole thickness of the derma have proved to be more satisfactory. These grafts are particularly useful over freshly denuded areas and under proper conditions will grow over fat, fascia, ligaments, periosteum and even bare bone. Padgett's dermatome¹³ used a new principle for the removal of thick split skin grafts. The instrument consists of a metal half drum with a 10 by 90 cm. curved surface. From it a sliding knife revolves over this surface and is adjusted by micrometer screws to cut at a determined distance from the curved surface of the drum. Rubber cement is spread

on the drum and on the skin and when these two surfaces become adherent by contact the skin can be pulled up and cut uniformly at any desired thickness. Parts of the trunk are thus made readily available as donor areas for skin grafts.

shiny or wrinkled appearance but the thicker the grafts are cut the more closely will they resemble normal skin.

Grafts of full thickness of skin (Wolfe-Krause grafts) if successful contract less and have a more natural appearance than

Fig 711—The author's skin rollers. The upper roller cut has a wide groove and the lower one a narrow groove for receiving the full thickness graft. The needle also at the bottom is adjustable and picks up the top of the full thickness graft and the skin is rolled up in the middle of the roller as it is dissected away.

With pressure dressings or with saline compresses granulating surfaces or freshly denuded areas even in the presence of infection as in the mouth or nose can be covered successfully by this type of graft. Wax molds fitting the defects and wrapped with these grafts may help to maintain the optimum pressure. Sterile sea sponges¹⁴ volu-

the other types of free skin grafts. However it is more difficult to obtain success with them than with the other types. The graft of the desired size and pattern is removed with a minimum amount of subcutaneous fat. The use of the author's skin roller (Figs 711 and 712) facilitates this removal. The donor defect is closed by undercutting on either

Fig 712—*a* Start of the removal of a full thickness graft. *b* The top of the graft has been caught on a needle and is being rolled on a metal roller. The roller can also be used for removing large nevi which do not extend beyond the depth of the skin.

minous fluffed gauze compresses or cotton waste placed over an immediate dressing of xeroform gauze is also used to obtain even pressure. These grafted areas may contract considerably and this property should be recognized and provision made for it by applying the grafts over a stretched denuded area. They may occasionally assume a dark

side and suturing or by split skin grafting and the full thickness graft is carefully sewn into the recipient defect. The graft should be equal to or slightly larger in size than the defect. An even satisfactory pressure must be maintained for a week or more with gauze or sea sponges over an immediate xeroform gauze dressing.

Free skin grafts folded with epithelium on the outside and wrapped in cellophane or phlofilm and then in vaselin gauze and sterile towels can be refrigerated at a temperature slightly above freezing and can be successfully transplanted days or even weeks later.¹⁶ Prolonged operations can thus be divided into two shorter operations as a life saving measure an extra operation can be eliminated by this means and a piece of skin left over from an operation can be utilized later if occasion arises.

Free skin grafts may be transplanted from one individual (a) to the same individual (b) to another individual of the same species or (c) to another individual of a different species. These may be termed respectively (a) autografts (b) isografts and (c) zoografts.*

Autografts under proper conditions should be uniformly successful. Although isografts have been reported as having taken successfully they usually fail to live more than a short time. Isografts of skin will often be apparently successful for as long as two to ten weeks and may then melt away. Sir Harold Gillies¹ reports the failure of a flap graft which had been transplanted from mother to child and had remained in position for a month. There is little hope of success with zoografts.

GRAFTS OF OTHER TISSUES

Other types of tissue such as mucous membrane fat muscle fascia cartilage and bone can be successfully transplanted by means of flaps provided sufficient nourishment for the tissues is maintained for instance a portion of the clavicle can be raised and transplanted as part of a pedicle skin flap. Muscle can also be transplanted in like manner with a skin flap or by itself to fill a depression. These types of tissues can likewise successfully be transplanted as free autografts under favorable conditions.

Mucous membrane is rarely used for free

grafting because skin can be made to take its place in most instances but if employed it can be taken from the lower lip or cheek and treated as a split skin graft.¹⁵ This tissue is more safely transplanted as a pedicle flap.

Free fat grafts are of great service in filling depressions. Dermal fat grafts whereby the lower portion of the skin together with the fat is transplanted or in the writer's hands fascial fat grafts with a sheet of fascia attached to the fat give a better chance of success than simple fat grafts. The lumbar region offers a satisfactory donor area for the fascial fat graft. Careful hemostasis gentle handling of the graft and freedom from infection are requisite in obtaining successful transplants.

Fascia grafts free from infection will take readily. They are useful for hernial repair either in strips as sutures in the Gallie Le Mesurier technique¹⁹ or as broad sheets of tissue to be sewn into defects. This latter type is of great service in the repair of large ventral hernias and in the reconstruction of serous membranes. Fascial strips may also be used to bridge over gaps in tendons to repair chronic dislocations especially about the shoulder joint and to restore the muscles about the mouth to a normal position in cases of facial paralysis.²⁰ The fascial lata is the most frequent donor area and the lumbar fascia can also be used. With the use of a fascial stripper such as that of Grace²¹ or of Masson long strips may be removed from the fascia lata through small incisions and in the writer's hands there has been no difficulty with herniation of the muscles of the thigh after removal by this method.

Tendon grafts may be successfully transplanted to replace gaps in tendons by using either whole tendons or portions of tendon. The palmaris longus tendon may be used with comparatively little functional damage and is often made to replace the flexor sublimis or flexor profundus digitorum tendons.²²

Free muscle grafts are used in small pieces to stop hemorrhage but they do not live as large transplants since they cannot be sufficiently nourished. Such grafts become infiltrated with scar tissue if they do not become infected and extruded. Flaps of the masseter or temporal muscles are used to

* Much confusion has arisen in the terms used to denote these three types of grafts namely (a) autoplastic grafts (b) homologous grafts (c) heteroplastic grafts (d) heterografts (e) heterologous grafts (f) xenoplastic grafts (g) xenografts (h) heteroplastic grafts (i) heterografts (j) zooplastic grafts. The writer has used the terminology of Dr. John St. George Davis in his *Plastic Surgery* as suggested by Dr. William H. Welch.

rectify paralysis of the muscles of the mouth and eyelids."

Where there is loss of continuity in an important nerve such as the seventh cranial nerve the proximal end of other nerves the spinal accessory or hypoglossal may be transplanted into the distal end of the affected nerve. Very gentle handling of the nerve with fine sutures of arterial silk to the sheath should be used. The disadvantage of this procedure is that a fairly important nerve is destroyed and there may be failure of regeneration of the transplanted nerve. Patients sometimes complain of inability to use the newly attached nerve even though the tract has regenerated. A whole section of nerve can be successfully transplanted with regeneration of most of the fibers if an extremely careful technique is used. In this case the transplanted nerve probably acts only as a conductor for the growth of the nerve fibrils.

Vens may be transplanted as free grafts for the purpose of covering other structures for instance as tendon sheaths round transplanted tendons to the fingers. They are also sometimes used as conductors of nerve fibrils when gaps in nerves occur.

The ease with which cartilage can be carved into a desired shape makes it much more satisfactory than bone for filling certain depressions about the facial bones and skull. Depressions of the bridge of the nose caused by syphilis (Fig 705) or some other infection by accident or by operation may be filled out by cartilage grafts⁶ after being carved to the proper shape and after the skin and subcutaneous tissue about the depression have been undercut (Fig 705 c f). The cartilage grafts may be introduced through an opening in the skin on the outside of the nose at its root or at the columella or through an opening made in the vestibule of the nostril after the skin and subcutaneous tissue have been undercut. Old depressed fractures of the maxilla malar bone or zygoma can be rendered normal in appearance by cartilage grafts. Cartilage for large defects may be removed from the ribs. The excess of cartilage removed can be buried in a subcutaneous pocket for future use or may be refrigerated. The somewhat more fibrous cartilage of the concha of the ear also can be used to build up smaller defects.

Cartilage preserved in mild antiseptic solutions such as merthiolite may be used either as autografts or as isografts to fill defects. There is some evidence to show that these grafts may eventually be replaced by fibrous tissue in contradistinction to fresh autografts and therefore might not be satisfactory when used for support. Dupretius working in our clinic has shown experimentally that young cartilage transplants will grow either as autografts or as isografts in young animals and as isografts in adult animals but that adult cartilage will not grow in any case. From this it may be deduced that cartilage grafts for growing children if they are to keep pace with the rest of the body should be of young rather than of old cartilage.

Bone frequently with the periosteum attached is used extensively in orthopedic surgery as free grafts. In plastic surgery it is of use for filling defects especially of the facial bones and skull. It must be absolutely free from infection in order to take successfully and in order to remain without absorption it must be held in direct contact with bone preferably at each end. Bone grafts may be removed from the tibia the ribs or the crests of the ilium grafts from the ilium being especially useful to replace losses in the mandible.⁴

Successful free corneal isografts have been reported with maintenance of transparency⁷ and with the recent development of a satisfactory technique they offer much hope for the restoration of sight to those with corneal scars.

ULCERS

(See also Section on Indolent Ulcers)

An ulcer is an area on an epithelial surface with partial or complete erosion of the epithelium which may extend into the deeper tissues and is attended by more or less suppuration. A wound or superficial loss of tissue due to trauma is not primarily an ulcer but may become such if the healing process is arrested or if the wound becomes infected.

It is our purpose here to deal not with those ulcers of the skin which are usually managed by the dermatologist alone but with the indolent ulcers of the skin which can best be treated by means of plastic surgery.

Many factors may be responsible for the production of ulcers, and usually there are two or more factors working together. These cutaneous ulcers which fail to respond in the usual methods of treatment may occur in the presence of such constitutional disturbances as diabetes, arteriosclerosis, general debility, and various blood diseases. The long continued use of certain drugs (mercury, potassium iodide, etc.) and diets lacking in vitamins may be productive of ulceration.

Other, more local predisposing factors are vascular disturbances (varicose veins) and neurotrophic changes (syringomyelia and nerve paralysis). Scar tissue is prone to ulceration particularly when exposed to direct violence from without the part or from the repeated excessive stretching of contractions. Malignant disease, such as rodent ulcer (basal cell epithelioma) and squamous cell epithelioma, produce ulceration. Conversely non-malignant ulcers of long standing frequently become epitheliomatous, probably because of constantly repeated irritation and the continued attempt of the part to heal by epithelial proliferation.

Trauma and infection are the most frequent exciting factors in the production of ulcers. Practically all ulcers of a chronic nature become infected either from without or from within the body by bacteria, fungi or protozoa. When to the predisposing factor and the exciting factor, such as trauma, there is added the complication of infection the ulcer tends to become indolent and difficult to heal.

Spirochetes (syphilis and yaws) and acid-fast bacilli (tuberculosis and leprosy), coming from within the body, produce ulcers of the skin, and the presence of either type should be determined and treatment provided. Hemolytic streptococci from without the body may cause acute gangrene of the skin, resulting in chronic ulceration.

The wounds caused by burns, whether from heat, chemicals, electrical currents or irradiation, are particularly prone to become ulcerous and even malignant. In the first three of these types of burns there is an immediate wound which may be very extensive and deep and which may heal slowly, with scar tissue formation. In an irradiation burn the break in continuity of the surface may be long delayed after exposure to the rays—

even to as long as twenty years or more. There is a series of progressive changes in the skin and deeper structures, the main features of which are sclerosis and an avascularization of the part, culminating in ulceration and necrosis. The changes in the tissues may extend beyond and beneath the ulcer and so may render difficult the spontaneous and induced healing.

In the treatment of these conditions all of the predisposing factors should be counteracted as well as possible. Diabetes should be controlled with insulin and diet, the person with general debility should be built up, if there is anemia transfusions may be indicated, varicose veins should be treated by sclerosing fluids (quinine and urethane) or by ligation.

In decubitus ulcers due to pressure the skin overlying the bony prominences should be protected from pressure by the use of rubber rings, doughnut rings of cotton and bandages and by frequently turning the patient in bed.

The ulcerated extremity should be elevated in order to produce an increased blood supply to the part. A moderate heat is helpful and may best be applied by light, such as "thermolite," or by a cradle supplied with electric light bulbs. Care should be taken not to apply too much heat so as to increase the ulcerative process. Chemotherapeutic drugs of the sulfonamide group given internally or externally or by both methods may control the infection. Penicillin may be useful. Many organisms in an ulcer, particularly anaerobic organisms, will clear up well with the use of zinc peroxide. This should be applied daily in the form of a thick cream suspension of the powder in sterile distilled water and should be covered with vaselin gauze to prevent drying and caking of the medication.²¹

The ulcer itself should be carefully cleansed. It will be found that there is often a growth of epithelium about the edges of the ulcer, but between the granulations and the epithelium there is a re-entrant angle which harbors organisms and which prevents the epithelium from adhering to the granulations. For this reason the epithelium should be cut back and any tendency for it to roof-over should be counteracted. Compresses of physiologic saline solution applied so that they come in contact with every part

of the wound may stimulate granulations to grow up to the epithelium and give the latter a chance to grow over the granulations. Dressings of balsam of Peru and castor oil in equal parts help to stimulate the growth of granulation tissue. Some ulcers will heal if covered over with narrow strips of zinc oxide adhesive tape sterilized by heat leaving slight openings for drainage. Some of the sulfhydryl containing compounds such as thiocresol²¹ cysteine hydrochloride²² properly buffered to keep the solution in an even and proper hydrogen ion range oxyquinoline²³ and scarlet red²⁴ stimulate the growth of epithelium so that an ulcer may be healed by these measures alone.*

Where the ulceration is progressive and is associated with a spreading zone of gangrene it is resistant to all the ordinary measures. A method of stopping the progress of this condition is to excise the diseased border with a wide margin. McLeney²⁵ has found that the progressive undermining ulceration with out gangrene due to the micro-organism hemolytic streptococcus can often be stopped by the use of zinc peroxide without requiring wide excision.

A chronic ulcer of long standing will have a base of dense scar tissue so that even if it has healed over it may break down again at the slightest trauma and the ulcerative process will be repeated.

The ulcers in the midst of scar tissue especially from thermal burns and those which resist the simpler therapeutic measures are best treated by wide and deep excision so as to leave only normal tissue at the base.²³ These ulcers for instance may extend completely around the lower part of the leg and it may seem very drastic to excise so widely. It will be a surprise however to see how universally these ulcers may be healed by such thorough excision and the immediate application of split skin grafts to the denuded area. It may in some cases be necessary to denude the tibia and such grafts as these will grow on the periosteum or even on the bone itself.

* Oxyquinoline scarlet red gauze applied once or twice a day is helpful. It is made as follows: oxyquinoline sulfate 0.6 Gm. chlorobutene (chlorobutanol) 2.4 Gm. liq. petrolol 10 4 cc. scarlet red ointment 5 per cent to 100 Gm. Mix and then impregnate gauze with the mixture in a dry steril jar.

At operation there may be found to be a great difference in the level of the grafted area and that of the surrounding skin but in time there is a leveling process which makes for smoothness of the entire area. If the freshly grafted area is covered over with a single layer of wide-mesh gauze fastened down around the edges of normal skin with collodion and covered with compresses of physiologic saline solution changed every four hours these grafts should take despite infection. Most ulcers can be treated in this way with excellent success if less strenuous measures fail.

There are times when a thicker pad than a split skin graft is needed over the excised ulcerated area and pedicle flaps will be found preferable to the free skin grafts or the flaps may be transferred after free skin grafts have healed. In particular an ulcer of the sole of the foot where continual trauma may be expected can best be treated by a pedicle flap from the other leg—the two legs being held in proper position by means of plaster of paris casts. Wide excision of the scar tissue about these ulcers prevents further return of the ulcer after exposure to ordinary trauma. In selected cases an ulcer or scar over the tibia can be excised and the defect can be covered with healthy adjacent skin and subcutaneous tissue by making relaxing incisions parallel to and at a distance from one margin of the defect. By undermining over the deep fascia a pedicle flap attached proximally and distally can be swung over the tibia and sutured to the other edge of the defect and the lateral defect can then be closed with a split skin graft.

It will be found that many ulcers of a chronic nature which have eventually become malignant do not extend below the superficial layer of the deep fascia and can be readily stripped off with a wide margin of uninvolved tissue about the ulcer to assure safety. However a biopsy should first be made in order to determine the activity, type and grade of the epithelioma. It may be advisable to remove the lymph glands to which the malignant ulcer drains. The denuded area left by excision of the malignant ulcer can be covered by a split skin graft or pedicle flap. If thorough care is taken to make a wide excision it may be

possible to eliminate completely the malignant growth in these slow growing ulcerations without having to resort to amputation of the part

SCARS CONTRACTURES HYPERTROPHIC SCARS KELOIDS

Scars are produced in the process of healing of tissue injuries and result in deformities which may be unsightly if visible. When disfiguring they may cause mental distress and influence the activities of the bearer.

There are congenital scars and those which are caused during life by accident by dis-

sent and this loss prevents the normal lubrication of the skin. The connective tissue fibers of scar tissue are more dense and less elastic than the connective tissue fibers of the skin. Trauma and the ravages of disease produce damage in scar tissue more readily and the lesions are more difficult to heal than in normal skin.

Langer²⁶ plotted the lines of skin tension on the human cadaver by making holes in the skin with a round awl and noting the direction of elongation of these holes (Fig 718). Scars which are linear and lie in the proper direction of skin tension tend to

Fig. 13—*a* Contracture of forearm in adult following burn in infancy. *b* perextens on of the hand on the forearm so that the distal end of the fifth metacarpal lies over the ulna. The contracture caused lack of development of the ulna and subluxated the radius at the radiohumeral joint. *b* x-ray of the forearm and hand to show distortion from contracture. *c* pedicle flap obtained from the abdomen after excision of the scar tissue to the wrist and hand. After lengthening the extensor tendons and tendon of the flexor carpi ulnaris and after excising 4 cm of the radius. *d* the hand in extension after division and revision of the pedicle flap.

ease or by intention as in operations. Should there be a combination of trauma and disease the resultant deformity will be greater. The amount of scar deformity depends on its extent and depth and also on its location. A scar over an exposed part is more disfiguring than such a deformity which is covered by clothing and different areas affected to the same extent may show varying degrees of deformity because of their position. With similar lesions the eyes and lips may thus be more distorted than the cheek or neck.

Scars are composed largely of connective tissue with a thin epithelial covering. Usually the sebaceous and sweat glands are ab-

spread but little, whereas those scars which lie in a different direction to these tension lines of Langer often spread unless the skin tension is completely overcome by careful suturing of the tissues in the depths. Operative incisions should be made if possible in the proper lines of skin tension. Whenever possible the wrinkle lines should be followed. It will frequently be found that an incision through the skin can be made in one direction and after the skin edges have been retracted important structures can be approached through an incision in another direction. Judicious selection of these directions will result in a lessened deformity.

Fig 714--Scar in the submental region from an ill advised median incision made to reduce a double chin. Note the spreading of the scar. Transverse incisions in this region are preferable.

Fig 715--a and b Pulsating scar following drainage of brain abscess through a trephine opening. After excision of the scar, a square area was countersunk in the bone around the trephine opening. Two rib grafts were used, one on each side, and held by a third "keystone" rib graft wired at each end, c and d, after treatment.

Where lacerations occur with displacement of tissue, care should be taken to replace the parts in their original positions as well as possible. Later adjustments may be made if healing has already taken place with the parts in malposition.

Larger depressions may demand undermining and filling out of the spaces with fat, cartilage or bone grafts. Other more extensive depressions can best be corrected by the transplantation of pedicle flaps, which may contain not only the skin and subcu-

Fig 716—*a*, Scar following crucial incision for a carbuncle of the back of the neck. Note the width of the scar in the median line and the narrowness of the transverse scar. The optimum incision in this region is approximately transverse, *b*, result after partial excision of two opposing flaps and advancement of two other flaps.

Depressed linear scars in soft tissue may sometimes be corrected by local plastic operations without the transfer of tissue from a distance. Incisions about these scars through the depressed skin and subcutaneous tissue should be made at right angles to the inverted skin surface so that when brought

taneous tissues but fascia, muscles and even bone. With loss of substance, replacement should generally be made with tissue which resembles the destroyed tissue as much as possible.

Small fistulas from the exterior to cavities lined with epithelium, as in the nose or

together the cut edges can be approximated throughout their extent. The upper layers of the scar tissue may often be excised, leaving the remainder as a foundation on which the undercut tissue on either side can be placed by drawing the subcutaneous tissue together with a buried line of sutures.

mouth, require an epithelial covering on the inner as well as on the outer surface; otherwise the area will heal by scar tissue and cause contraction. If the fistula is small, the epithelium around its orifice may be undermined and reflected to cover the inner opening. Undercutting of the surrounding exterior

tissues may then allow simple closure to be made. If the denuded area caused by turning in epithelium-covered flap is too large to permit this a pedicle flap can be used to close the external defect. Should the size of the fistula be so great as not to allow this type of closure a pedicle flap previous

be stimulated until a satisfactory bed is obtained. Excessive granulations should be reduced by the application of a silver nitrate stick or by excision. While the area is being made suitable for grafting contraction of the parts should be overcome by maintaining them in hyperflexion or hyperextension

FIG. 19.—Showing the lines of normal tension of the skin known as the lines of Langer. Incisions that cut the skin across these lines will gape wider than those cut parallel to them and unions closed parallel to these lines will be less likely to encourage scars than those closed across them. The elasticity of the corium throws the papillary layer into definite folds which cause these patterns. The epidermis plays no part in the formation of these folds, as it merely covers the corium beneath. These patterns are practically uniform with only minor local variations.

made with skin on both sides may be used. This flap may be formed either by reflecting the end of a skin flap on itself or by transplanting a full thickness graft to the under surface of a flap (Fig. 708).

When extensive injury has caused wide destruction of skin granulation tissue should

to prevent subsequent limitation of motion by contraction. Grafts should be applied at the earliest possible moment. This early grafting hastens recovery and lessens the growth of dense immobile scar tissue. If free skin grafts are to be applied thick split

• Davis and K. Bowler: Arch. Surg. 23

skin grafts will heal more rapidly and give a better appearance than small deep grafts. Pedicle flaps may be used subsequently if required.

As scar tissue limits development in growing children, its early removal will tend to allow normal development of the affected part.

After epithelization of a wound has occurred, the underlying scar tissue continues to contract. This may sometimes be helpful, but occasionally the contraction may distort surrounding tissues and cause loss of function by limiting motion. This functional loss oc-

By this means the scar is lengthened, and with longitudinal pull on it, an accordion-planted effect will take place.

Transverse incisions through broad scar contractures, with judicious lateral undermining, may relieve the tension of the contractures. The denuded areas can be covered by thick-split skin grafts, by whole-thickness skin grafts or by pedicle flaps. Flaps tend to contract less than free grafts.

Hypertrophic scars and keloids are unsightly and are sometimes difficult to overcome. The hypertrophic scars are composed of small collagen fibrils, whereas the keloids

Fig. 710—*a* Single Z incision with transposition of flaps to overcome the "bow-string" effect of a linear scar at the elbow. The scar is excised and after an oblique incision is made at each end the flaps are transposed and sutured. The resulting scar is doubled in length, and on extension "an accordion-planted" effect is produced. *b* the double Z incision with transposition of flaps is frequently found to be more advantageous than the single Z incision.

curs particularly when the contracture is in the neighborhood of joints especially over the flexor surfaces.

Scar tissue by its contraction may cause pain when nerves are affected and may even produce paralysis of nerves. Depending on its extent and depth, scar tissue may cause more or less loss of motion of the outer surfaces over the deep structures.

Longitudinal linear scars over flexor surfaces about joints may cause a bowstring effect by their contraction. Excision of the scar, with Z incisions and transposition of flaps, may overcome the bowstring effect²⁹

have large collagen fibrils. The factors producing hypertrophic scars and keloids are not fully understood. Some persons have a greater tendency to produce them than others. Keloids, when excised, almost always tend to recur, with an increase in size, and excision is contraindicated unless appropriate measures are taken to prevent this return. Some surgeons reduce hypertrophic scars by the application of trichloroacetic acid, but this may increase the growth of keloids.

Both the hypertrophic scar and the keloid respond to irradiation and may be reduced

in elevation and softened by this means alone. The keloid is usually best treated by means of excision followed by irradiation which is given over a long period. Great care must be taken not to burn the patient. Several treatments with small dosage are safer than fewer treatments with heavy dosage. A satisfactory method is to cover all but the raised area with a lead shield and give a roentgen ray treatment with a dosage of 100 r once every two weeks for two months followed by a months rest. Later courses of four treatments can be given if needed. The earlier irradiation is given after excision the more effective will it be.

TATTOO MARKS

A tattoo is an indelible mark made by puncturing the skin and introducing some pigment such as carbon into the punctures. If the pigment cannot be absorbed by the body it produces a lasting mark. Coal miners are unwittingly disfigured in this way. Gunpowder and dirt may also be embedded in the skin accidentally. The accepted meaning of the term tattoo mark, however, is a mark produced intentionally by a more or less expert person by introducing foreign bodies beneath the surface of the skin with needles usually in designs or patterns. Because of uncleanly methods used infection and syphilis may develop in the tattooed areas.

Many people especially sea faring men under the influence of alcohol allow themselves to be tattooed They often regret the step when sober and subsequently wish the tattoo marks removed

If the foreign bodies lie in the upper layers of the skin they can be removed by one of several methods. The skin containing the foreign bodies may be shaved off with a razor or large knife as in the removal of a thick split skin graft and if very superficial only slight scarring will result. The more deeply the skin is removed the more pronounced will be the scar. Another method is that of tattooing the mark with a 0.5 per cent solution of tannic acid and after protecting the surrounding skin with vaselin rubbing in a silver nitrate stick.²² A thick eschar forms subsequently and may carry with it the foreign bodies when it comes away. This method is unsatisfactory when

the deeper layers of the skin are involved and unfortunately in most cases the pigment is carried deeply into the skin. If the pigment is deeply embedded and the tattooed area is of small size it can be excised and the defect closed by undermining on both sides and approximating the skin edges, and the subcutaneous tissue with two or three layers of sutures. Larger tattooed

Fig. 20—Release of an armadillo at all four on the mark II station of motion. Wavy lines are male and pectoral and scapular flaps are also released and before operation and after per to.

are may require culture extension and the covering of the defects with thick split skin grafts, full thickness grafts or thin flap grafts.

Foreign bodies such as powder granules and dirt accidentally introduced in wounds should be carefully and completely removed at the first treatment. If however the wounds have closed with these granules embedded the scars may be excised or if the granules are embedded only in the upper layers of the skin they may be shaved off in the same way that a thick split skin graft is removed.

REPAIR OF DEFECTS OF THE FACE.

HANDS AND FEET

THE FACE

Congenital clefts of the face result from persistence of embryonal fissures. The most important clinical defects are *cleft palate* which results from non union of the palatine processes and *cleft lip (harelip)* which results from non union of the maxillary and globular processes. It is well to remember that these regions are normally fused by the eleventh week of embryonal life, because

some of the most convincing maternal impressions may be given to account for the occurrence of a cleft lip or palate.

The actual cause of these clefts has not been definitely determined although many theories have been advanced. The most constant finding is that heredity apparently plays an important role and that multiple cases may occur in the same generation. This point is important as a guide to prognosis for parents who are interested in determining the chances of having a normal child if there are cases of cleft in either family or if the parents have already had one deformed child. However no definite percentages are available in this regard.

Figure 721 represents the various possible facial clefts in relation to the embryonic clefts. Many different degrees of each type can occur. Cleft lips are the most common but there can occur microstomia, lateral facial cleft that may extend clear through the eye socket very rarely median cleft of the upper lip and perhaps most rarely median cleft of the lower lip.

Cleft lip and palate may occur in a great many forms ranging from a notch in the uvula or the lip to a wide open cleft of the lip alveolus and palate (single or double). Attempts have been made to classify all types but the best record is a simple diagrammatic representation of each type of case.

Repair of the Cleft Lip—Early closure of the lip is important in that it allows the mother to exhibit her baby without apology; it helps control respiratory infection and feeding is made easier for both the mother and the baby. If a lip is closed soon after birth over an open alveolar cleft nothing being done to the bone the alveolar arches will be compressed into approximately normal position by the pressure of the lip within twelve months in most cases. Although the procedure is difficult in small infants the advantages to the baby and its mother outweigh the disadvantages to the surgeon.

The specific objectives of the operation should be to bring about the best possible immediate restoration of the lip and floor of the nostril. If this is well accomplished subsequent growth should further improve the result by bringing the external nose to the midline and gradually closing the open alveolus.

Figure 722 illustrates the modification of the Mirault operation which the writers employ in nearly all cases.

Figure 723 illustrates the simplest type of operation for cleft lip and is the one recommended if the operation is undertaken without experience.

Secondary operations are necessary in a large number of cases. If there has been no early correction of a harelip or if the correction has not resulted in good nasal contour there will occur a deformity that becomes worse and more solidly fixed with the growth of the face. This deformity is perhaps worst when there has been an early forceful closure and wiring of the spread maxillae. The surgical correction necessitates an extensive procedure with complete freeing and rota-

Fig. 721—Diagram to represent the possibilities of facial clefts in relation to the embryonic clefts (Meckle).

tion of the nostrils into position. If there are not sufficient or properly placed teeth to maintain a normal profile of the soft parts a dental prosthesis may be necessary for additional support.

Repair of the Cleft Palate—Repair of a cleft palate is performed by the writers before the second year but the time varies among other surgeons from the fourth month by those who use a direct bone wiring procedure up to the fifth year by those who do not think that bad speech habits are influenced by this delay. Factors in favor of the late operation are a lower mortality and greater ease of operation. The Dieffenbach-Warren operation may be taken as a standard procedure (Fig. 725). In the procedure

of Veau, which has wide acceptance, the front part of the palate and the space between the alveoli are closed at the time of defect of the palate requires wide mobilization of the tissue and accurate suturing to insure success

Fig 722—*a* and *b* Modified Muhlert operation Point *A* is located across the base of the columella *B* is at the lower end of the philtrum and *C* is half way between *1* and *B* *A* is at the junction of the inside and outside of the alveoli *AC* and *CB* are the equal distances of *AC* and *CB* with *B'* on the vermillion border *BZ* and *BZ* are incisions to permit interlapping of the vermillion border and thereby prevent notching *AC* can be curved if there is very little tissue available *c* The dotted line shows the necessary undermining The suture is being passed to engage the muscle and establish the level of the floor of the nostril This procedure is somewhat difficult to carry out but there is minimum sacrifice of tissue and there is less apt to be a notching of the lip and general lack of tissue than with many other procedures

Fig 723—Huxson Nose type of operation, perhaps the simplest method of repair

Fig 724—Complete double cleft of lip and palate with premaxilla and proboscis entirely out on the tip of the nose Correction shown after a one stage procedure removing all vermillion from the proboscis At a later date the columella can be advanced unless it develops spontaneously In these cases the premaxilla should never be excised

the lip operation and the soft palate later The closure under the lip and through the alveoli is done on the writers' service at the time of the closure of the palate or at a later date if necessary The repair of a small

Speech training for every patient with cleft palate is essential To produce normal speech, the nasopharynx must be closed off except for a few sounds that are normally directed through the nose This closure is

Fig 720—*a* Mobilization—Warren's approach *b* Mobilization—elevation of the mucoperiosteal flaps The point of the angle elevator enters the lateral incision just in front of the postpalatine foramen and then by working forward the mucoperiosteum and with it the palatine artery can be freed from the underlying bone as far forward as the incisive foramen *c* Mobilization—division of the palate aponeurosis *d* Denudation—of the cleft border by paring *e* Suturing—the uvula and upper surface of the velum *f* Suturing—the mucoperiosteal flaps The mucoperiosteal palate flaps are united with vertical mattress sutures bringing several millimeters of the raw upper surfaces into contact. It is at the junction of the velum with the mucoperiosteal flaps that one is most likely to have failure of union owing either to insufficient relaxation or a deficient blood supply, and it is to be remembered that tight suturing interferes with the blood supply (Blair and Brown Surg., Gynec. & Obst. 59:309, 1934). If there is any doubt of the integrity of the major palatine arteries it is safer to suture as far forward as the original relaxation will permit without tension and to do the remainder at a subsequent stage as failure of union is less catastrophic than a slough or a distorted flap.

naturally performed by a sphincter action of the levator palati, pharyngeal constrictor and palatopharyngeus muscles, therefore, the aim of the operation should be the pro-

duction of a long palate with a mobile soft part. Unfortunately in many results obtained after repair of the palate the pharynx is far from closed and speech is still

hindered by the leakage of air into the nose. It is a great advantage to place the patient under the direction of a speech trainer but if this is not possible the mother can learn the essentials and then train the patient at regular intervals.

Elongation of the Palate—In an effort to afford better nasopharyngeal closure during speaking several operators have described methods for elongating the palate. Dorrance's procedure which he calls the push back operation is best known. It consists of making a delayed flap of the entire front part of the palate with sacrifice of the major palatine arteries at the first stage. In a second operation the whole palate is raised

Some surgeons have carried out the procedure in cases of complete cleft and have left a hole anteriorly that has had to be closed with a dental obturator. In suitable cases of complete cleft the elongation can be carried out after the cleft has been closed by splitting the palate in two care being taken to leave the nasal mucosa intact and then setting the palate back without leaving an opening anteriorly.

Pharyngoplasty has been advocated mainly by Wardhill to constrict the nasopharyngeal opening by making a transverse opening on the posterior pharyngeal wall and then reefing toward the midline the mucosa and superior constrictor muscle.

Fig. 726—A The whole palate has been loosened from the bony palate, the nasal mucosa opened, the major palatine arteries preserved and the suturing started to carry the palate back. B The palate is held back with three to five sutures and the exposed bone in front is allowed to cover over. Healing is usually complete in one month. C The elongated palate is shown with the posterior opened space much smaller than it was originally (Hirwin).

again pushed back toward the posterior pharyngeal wall and anchored there and the cleft is closed. This procedure is used also when the palate is not cleft but so short that cleft palate speech results. Dorrance calls this condition congenital insufficiency of the palate.

Another method of elongation is shown in figure 726 in which a direct flap is taken with the major palatine arteries preserved and the whole palate moved backward at the first operation. When possible the cleft is closed at the same time so that only one operative procedure is necessary.

These elongation operations are mainly applicable in cases of partial cleft in which the bony palate will be left in front to preserve separation of the nose and mouth.

Reconstruction of the Lips—The blood supply through the coronary vessels makes it possible to switch vermilion bordered flaps from one lip to another in order to improve the proportional amounts after removal or loss of skin from one lip. If the defect is near the angle a triangular piece can be swung directly into place preserving the coronary vessels in a mucous flap. In such cases the pedicle of the flap will form the new angle of the mouth. The donor lip defect is closed by pulling the lip over to the cheek with the making of any further adjustment necessary to lessen the distortion about the nose and upper part of the lip. The corner of the mouth is put in the best obtainable position but this may be improved if necessary by subsequent opera-

tion The suturing should insure contact for the full depth of the wound (Fig 727 n) If the defect is near the middle of the lower lip the remaining lateral portion may be raised as a somewhat rectangular flap and

obtained by bringing in a flap of suitable size from the scalp forehead or chest Figure 729 illustrates the use of a scalp flap in a man in a woman a flap from the forehead is used

Fig 727—*a* The lower tranche is excised and the one from the upper lip is swung directly across. The adjustment under and at the side of the nose is to improve nasal balance as the skin is a sagged flap. The operation is made and the closed flap is to be held open.

swung across to fill in the center. The defect at the side of the lip can then be filled in with a flap from the upper lip (Figs 727 b and 728). When a flap is swung directly from one lip to the center of the other the pedicle must of course extend across the mouth and remain there until the flap has established its new blood supply. It is usu-

Reconstruction of the Nose—The nose is the most conspicuous feature of the face and any exaggeration of size or deformity makes it a target for undesired attention and is likely to produce a deprecatory or disquieting self-consciousness. The general plan of correction for a nasal defect should always be worked out before the decision to

Fig 728—Patient on whom plan shown in figure 72 was used after a lateral rectangular flap had been selected over to the center.

ally cut in two or three weeks. For complete reconstructions these flaps may be used in combination with others of the full thickness of the cheek, which are advanced along the jaw, or flaps from the face alongside the nose with the base down may be put entirely across the defect. The most satisfactory result for a full restoration is usually

obtained by bringing in a flap of suitable size from the scalp forehead or chest.

Saddle Nose—A depression of the bridge of the nose may occur as a result of injury, the formation of a septal abscess, resection of the septum and destruction of the septum (and mucous lining) due to syphilis. For building up the defects the transplant

tion of autogenous fresh cartilage is usually employed although fresh homografts and preserved homografts may prove successful.

Hump Nose—An unsightly nose as a family or racial characteristic often constitutes sufficient worry to the patient to war-

shortening of the septum to reduce the length of the nose. After removal of the bony hump it is necessary to reduce the width of the upper part of the nose by moving in the nasal bones. In proper hands the operation results in marked improve-

Fig. 29—*a* Complete loss of the lower lip and chin from paste treatment for cancer. *b* Restoration with the pedicle scalp flap. The lining was obtained by turning in the scar and epithelium. *c* Final result: a watertight mouth. The defect of the scalp is covered with a single large split graft. If desired a vermilion border can be obtained by turning a mucous flap from the inside of the upper lip.

rant correction. The correction in each case must be planned according to the deformity of the nose and the balance of the patient's features. In almost every instance all struc-

ture in appearance and is usually very satisfactory.

Deformities Resulting from Fractures—It is possible that in most cases an apparently unexplained severe nasal deformity is the result of an untreated fracture sustained early in childhood. The mechanism is probably a crushing in of the nasal bones and frontal processes with impingement on and perhaps fracture of the cartilaginous septum. If not corrected this deformity frequently becomes worse with marked distortion of the septum and deviation of the nasal bones.

Total Reconstruction of the Nose—The main causes of total loss or destruction of the nose in the writers' series have been cancer and its treatment, syphilis, tuberculosis, automobile injuries, bites from animals, and human fights, paraffinomas, burns, and excessive irradiation. There has been one undiagnosed case of necrosis and one case of necrosis several years after an implantation (by another surgeon) of some metal for a depressed bridge.

The diagnosis in this group should involve a study of the surrounding field to determine, for example, whether or not any further disease or new growth persists. If the destruction has been due to a basal cell carcinoma, extreme care should be taken and

Fig. 750—Restoration of a saddle nose with a pedicle flap from the arm for lining and costal cartilage for support.

tures of the external nose are reduced in size or changed in shape. Such a correction involves removal of the bony and cartilaginous hump, shortening of the upper lateral cartilages, reduction in size or change in shape of the lower lateral cartilages, and

if necessary, further treatment or destruction employed. In this region, basal cell growths are notoriously apt to return. This is also a field for the occurrence of mixed types of growths, the basal-squamous carcinomas. If the surgeon during a repair operation finds evidence of a recurrence deep in around the pyriform fossae or down along the wall of the nose, the work must either be delayed or abandoned entirely and further steps taken for the control of the growth.

The plan of repair is always, if possible, to use a delayed flap taken from the forehead and to use skin surrounding the defect as the lining of the nose by turning in small delayed flaps. Flaps from the neck, chest and arm are used only if necessary.

ample, whether a pedicle flap or a free skin graft will suffice, and whether transplants of bone, cartilage or fascia may be necessary. This phase must be accurately fitted in with the availability of tissue for making the repair and further with the general physical condition of the patient for standing long operative procedures.

Burns of the face and neck can be repaired in most instances with free, full thickness or thick split skin grafts, but pedicle flaps are used by many operators (Fig. 731).

Types of Free Grafts—The *Ollier-Thiersch graft* is very thin and includes the epidermis and nearly always some of the derma. The statement found in most texts that the Thiersch graft is cut above the

Fig. 731—*a* Complete burn of the front of the neck with open bite of the lower jaw due to the pull of scar tissue. *b* method of dressing free skin grafts. This was the first postoperative dressing; the outside heavy gauze fixation has been removed and the sea sponges used for pressure are seen forming a cast of the area. *c* full restoration of the skin from the chin to the sternal notch; complete function and spontaneous correction of the open bite after release of the pull of the scar. The deformity was completely released first with thick-split grafts and later, to effect better smoothness, a full thickness graft was put in entirely across the neck.

Congenital deformities occur in great variety—blockage of one or both nostrils, half nose, double nose, split nostrils, total absence of a nose and the deformities attendant on ocular hypertelorism.

The Repair of Deformities of the Face.
—The multiplicity of deformities about the face and the rather complicated procedures of repair prevent any very complete discussion of each type in the present text. The principles of repair, however, are not difficult and may be considered briefly. A diagnosis must be made of the condition just as for any other surgical lesion. There is necessity for a careful study of the deformed or missing area in order to determine its extent accurately. Next, the possibilities of repair must be painstakingly considered, for ex-

ample, whether a pedicle flap or a free skin graft will suffice, and whether transplants of bone, cartilage or fascia may be necessary.

The *full-thickness graft* (Wolff-Krause) includes the full thickness of the skin down to the subcutaneous tissue. It can be cut accurately to pattern and, if successful, gives the best repair of any type of free graft. It must be applied without any attached fat and requires careful postoperative attention.

Between the thickness of the *Ollier-Thiersch* and the *full-thickness graft*, one may be obtained that possesses nearly all the ease of application of the *Ollier-Thiersch* graft and many of the virtues found in the *full-thickness graft*. This graft may be from one third to three fourths the thickness of the skin and might be called a thick *Ollier-*

Thiersch graft. To distinguish it from the true thin Thiersch graft, however, the writers have called it a *thick-split graft*. It can be cut rapidly in large pieces, and the area from which it is taken heals promptly

Calibrated Grafts.—Recently the Padgett dermatome has become popular. This instrument enables a relatively inexperienced surgeon to cut a split-thickness graft of fairly uniform nature and thickness. It is

Fig. 732.—Method of cutting a thick-split skin graft. The main essential is a long, very sharp knife, the skin is lightly greased, an assistant holds firm traction on one end and the operator slides his traction along ahead of the knife. Here a suction retractor is being used which is a vacuum box attached to a suction machine.

without distortion. The thickness and cutting of this graft are shown in figures 732 and 733.

Deep defects of the face, especially those involving the full thickness of the cheek or

also valuable for removing such grafts from donor sites unsuited to free-hand cutting, namely, chest wall, abdomen and back. The principles involved in getting a successful "take" or result from the graft so obtained

Fig. 733.—a, Thickness of the usual Oller-Thiersch graft. It contains a small amount of dermis and is not cut through the papillae. b, a thick-split graft, in this instance, about two thirds of the full thickness of the skin.*

those extending deep in the orbit, require pedicle flaps for adequate repair, and in the case of full-thickness loss of the cheek, the repair must of course be lined both inside and out.

are not altered. The Caltagirone knife has been constructed for the same purpose.

Deformities of the Jaws.—An open-bite deformity may result from the pull of scar

* Surg., Gynec. & Obst., 50

tissue in the neck and if this is simply released the occlusion of the teeth may be spontaneously corrected (Fig 791)

In ankylosis of the temporomandibular joint the jaw is pulled to the ankylosed side and flatness results on the opposite side. After correction of the ankylosis by resection the deviation remains and the facial contour may be greatly improved by implanting a piece of costal cartilage along the outside of the jaw on the flat side.

Loss of substance of the jaw allows collapse of the remaining fragments toward the midline. For restoration there must be complete healing, adequate soft tissues available

and placing the free end of the cartilage high up in the region of the glenoid.

Retraction of the lower jaw can be done what corrected by osteotomy of the ramus with a shifting forward of the lower on the upper fragment and maintenance of firm fixation until union occurs. The profile can be further improved by implantation of cartilage over the chin.

Prognathism or excessive prominence of the lower jaw is corrected by removing a full thickness section from each side of the jaw and maintaining the fragments firmly until there is solid union. In the upper jaw it may be necessary to extract teeth, remove

Fig 791—*a* Facial paralysis of the type at left; *b* of an expressionless face parallel to one side by the use of muscles. The lower lid of the right eye is paralyzed and has been supported with a tape on strips of fascia lata. There is still no emotional expression, but there is great relief from the sagging tissue.

to receive a bone graft, adequate separation and preparation of the remaining fragments and adequate fixation of the jaw usually by means of dental splints. For restoration of the chin and body the writers have used the angle of the scapula, but this is not recommended, a free graft of bone from the rib, humerus or tibia being preferable. Occasionally for small defects a pedicle graft of a section of one of the fragments with the platysma muscle left attached will suffice (Cole).

For complete loss on one side a section of the seventh rib with its attached cartilage can be used, the bone being fastened to the fragment in front, letting the costochondral junction suffice for the angle of the jaw

the prominent alveolus and substitute a dental prosthesis.

Facial paralysis which is not amenable to nerve suture or anastomosis can be greatly improved by implantation of strips of fascia lata which traverse the cheek from the temporal or parotid fascia to both lip, the angle of the mouth and frequently around the lower orbital border and are then looped back to the fascia and fastened with enough tension to correct the distortion due to the pull on muscles from the opposite side. A method of fixation of fascial strips into the temporal muscle which is innervated by the fifth nerve has been successful even to the point of producing some emotional expression.

Defects of the Scalp.—Defects of the scalp can nearly always be repaired with free grafts, either thick split or full thickness. Free grafts will not grow on bare bone, even where there is fresh denudation of periosteum, and if it is recognized that the periosteum is stripped up, grafting should be delayed until granulations or scar epithelium covers this area. If there has been a wide burn with loss of hair, it is best to resurface the area early, because scar epithelial healing may never prove satisfactory.

Late distortion of the scalp, forehead, eyebrows and lids may be corrected by re-

thick-split grafts. It will be found that the scalp will not shift unless taken up from the periosteum, and as free grafts will not grow on bare bone, it is important not to strip up periosteum accidentally when raising the flap (Fig. 735).

Abruption of the Scalp.—This not uncommon injury results when the hair is caught in moving machinery. If the periosteum of the skull has been removed, then one must wait for granulations to develop before applying a skin graft. If the periosteum is intact, the area may be covered with a skin graft immediately or later on the granulat-

Fig. 735.—*a*, Deformity following osteomyelitis occurring after an operation on the frontal sinus. Both plates of the skull are missing over the area of thin scar in the center. *b*, repair was effected by shifting large scalp flaps to obtain a normal eyebrow level and to cover the dura with full thickness scalp instead of the thin scar. Skin graft repair was necessary over the vertex, where the flaps were obtained. In shifting large scalp flaps, serious hemorrhage may occur, and the procedure should be executed with the greatest care.

lease of the contracture, replacement of the tissues, especially the eyebrows, in their normal position and filling in the resultant defect with a full-thickness or thick-split skin graft.

Wide loss of scalp tissue resulting from the use of flaps for repairs of the face from the removal of moles and other growths may all be restored with thick-split grafts.

Bony defects are usually associated with loss of scalp tissue, and many unsightly deformities can be improved by the shifting of tissue to fill up an uneven contour and by replacement of any open areas with

ing wound. In no case has the replacement of the avulsed scalp as a free transplant been successful to the point of having the healed defect covered with hair. One instance is known in which the avulsed tissue was thinned until it resembled a split-thickness skin graft and was then replaced; a partial "take" occurred, but there was no growth of hair.

Reconstructive Surgery of the Orbital Region.—The satisfactory surgical correction of defects about the orbit may necessitate some of the most complex and trying procedures. The complicated anatomy

and physiology and the wide variety of lesions—congenital and acquired—make careful planning and execution of the details of reconstruction imperative; only the common types can be included here.

Ptosis.—In the congenital type of ptosis there is lack of action of the levator palpebrae muscles, so that the pupil is covered by the lid most of the time. The patient may not use the eye at all, but he can attain

gliomas, neurofibromas, mixed tumors and dermoid cysts

Epicanthus is due to vertical shortness of the tissues inside the inner canthus. There is an apparent redundancy of tissue in the transverse direction, but in the surgical correction, too much tissue is never found. The usual type is congenital and may be accompanied by ptosis, another congenital variety accompanies total or partial absence

Fig 736—Congenital ptosis corrected with a fascial loop fastening the tarsal plate to the frontalis muscle

some elevation by arching the eyebrow with the frontalis muscles. He can also hold the head back so that the pupils may be directed downward, or a child may even use his finger to elevate the lid out of the line of vision. Various plans have been proposed for elevating the lid, but perhaps the most satisfactory is the use of a fresh autogenous strip of fascia lata looped through from the frontalis to the tarsal plate to connect the

of the nose. Traumatic epicanthus may result from a depressed fracture of the nasal bridge. This type may be relieved by building up the nasal bridge, but if there has been loss of tissue, frequently there must be replacement by either a free graft or a flap.

The correction of the congenital type usually depends on a careful flap operation in which one or two flaps are taken from the transverse fullness and switched so as to

Fig 737—Epicanthus corrected by a local flap operation of splitting the web in two and reversing the two surfaces, making them transverse instead of vertical

paralyzed lid directly with the active forehead muscle. If there is thought to be enough levator action to raise the lid, the simplest procedure is to shorten this muscle.

Ptosis may also occur from trauma, and the correction may be extremely difficult if there is scar fixation of the lids or contraction of the socket following loss of the globe. A tumor may encroach on the lid so that elevation is impossible; the most frequent types of these are hemangiomas, lymphan-

replenish the vertical shortening. It has been claimed by others that correction of the natural epicanthus of Chinese has been satisfactorily accomplished by plication and removal of a crescent of tissue over the bridge of the nose.

Depression of the orbit from fracture, with or without the loss of the globe, forms a difficult type of facial lesion to correct if displacement is great and fixation has become firm.

A heavy blow on the orbital border usually drives the zygoma down and back and usually at least three fractures result—at the zygomatic maxillary suture line at the zygomatic frontal suture line and at the suture line between the zygoma and the zygomatic process of the temporal bone. The fracture may even extend down around the walls of the antrum with marked comminution.

When the orbital floor is depressed the globe of course follows it and diplopia may result. This is the most important physiologic derangement that occurs in these injuries and an effort should always be made to correct it. In a fresh injury the orbital floor and border are carried back into place by introducing a sound into the antrum

result from syphilitic (or other pathologic) destruction or from trauma. The deformity causes eversion of the lid and exposure of the globe that cannot be overcome entirely even by forced muscular action. The main object of correction is the replacement of tissue so that the lid conjunctiva may settle back down on the globe and provide normal protection for it. This is carried out by complete relaxation of the scar so that the tarsal border freely covers the globe and then by covering the defect with tissue of suitable size and thickness. The material used in order of frequency are (1) free thick split grafts applied over wax forms, (2) free full thickness grafts, (3) pedicle flaps from the forehead and (4) double pedicle flaps from the skin of the opposite

Fig. 39.—Ears set back in one operation by elliptical excision on skin and cartilage from the posterior surface.

through the buccal fornx and forcefully elevating the border. An iodoform pack is then introduced carefully to act as a splint and is left in place for two weeks. If there is a normal antral opening into the nose the fistula into the antrum will close spontaneously. If fixation is allowed to occur with marked depression the sight of the eye may be useless (except for monocular vision) because of derangement of the extrinsic ocular muscles. Along with this trouble there is marked facial deformity that demands correction. If the vision or the globe has been lost the correction is entirely one of restoration of the contour and the correct height of the orbital floor for the prosthesis.

Loss of the surface skin of the lids (ectropion) usually results from burns but may

also result from trauma. The deformity is usually corrected by free full thickness flaps from eyelids.

Eyebrows are practically always replaced with free full thickness grafts from the scalp. Only infrequent attempts are made to replace eyelashes.

Deformities of the Ears.—Congenital absence of an ear associated with failure of the development of the whole side of the face and jaw is the worst deformity of this region. There may be no external ear canal and it is perhaps best not to investigate the region surgically for fear of damage to the seventh nerve. The external restoration of an ear absent from this or any other cause is a tedious procedure and the final result at best is only an outline. However, in men the absence of an ear is such a noticeable

deformity that and is usually sought. The repair is accomplished with flaps from the local region and the neck and with costal cartilage.

The most common deformity of ears is excessive prominence and here again especially in boys and men the correction may be very important more so if it exists only on one side. The operation consists of an

REPAIR OF SURFACE DEFORMITIES OF THE HANDS AND FEET

Burns are responsible for a large and very important group of deformities of the hands. As soon as they are seen every effort should be put forth to prevent the deep infection that will so rapidly fix tendons and joints and produce deformities that may never be overcome. For deep losses the first treat-

Fig. 30.—a A burn of the hand caused by a mangle about twelve days after the accident. b After two days of saline soaks, saline jelly, dressing and gentle debridement. c Final result from application of a single thick-skin graft. The patient was able to work after five weeks.

elliptical excision of skin and cartilage from the posterior surface.

An annoying deformity is the persistence of an open wound and hole following a mastoid operation. The correction can be made if there is complete healing by filling the defect with a flap of scalp taken from the occipital region after the hair-bearing skin has been removed and then covering it with a hairless skin flap from behind the ear along the edge of the wound.

ment should be active surgical drainage. Active movement should be encouraged; the fingers should be dressed separately and the whole hand kept in the position of function. The average burned area should be ready for grafting in three weeks if tendons have not been exposed and frequently the single application of a split graft may be all that is necessary. If there has been an extensive deep burn as soon as sloughed tendons have separated and the granulations are clean it

is often advisable to "dress" the wound with a thick-split graft, so that healing may stimulate activity and joint fixation may be limited, then later any necessary thicker repair can be undertaken (Fig. 739).

notably advocated by Kanavel, Koch and Mason.

X-ray Burns.—Radiation burns are found most frequently in doctors and respond best to wide excision through the full

Fig. 740—*a*, Extremely bad x ray burn of the hand of a physician. The second and third fingers have already been removed because of carcinoma and active growth is now present. *b*, result of partial amputation removal of all skin of the dorsum of the fourth and fifth fingers and application of a thigh flap. The outflung graft higher on the dorsum is a one year old thick split graft put in later; *c*, ten day old split grafts on the opposite hand of the same patient. *d*, same hand as shown in *c* after one year.

The rehabilitation of the patient's activities should be started early, even before surgical restoration is started, if possible. Children usually take care of their own problems, but guidance in physical and occupational therapy is always beneficial. The use of splints may be required, as

thickness of the skin and repair with thick-split grafts. This procedure eliminates not only the individual keratosis but also the intermediary damaged skin. Small, isolated keratotic spots are removed with the actual cautery or electric current, and spontaneous healing is awaited.

Carcinomatous changes in the irradiated tissues may further complicate the problem. The simple superficial epitheliomas will not, as a rule, require excision deeper than the subcutaneous fascia, and the resultant defect can be immediately repaired. In dealing with these, it is usually best to include in the excision the whole area of damaged skin and immediately replace it with a pocket flap

can be carried out on the toes, but it is usually not necessary to do so.

Constricting Bands.—Constricting bands occur from small constrictions of the tip of a finger or toe up to very heavy complete circular indentations at the wrist or ankle or above. The cause is often said to be embryonic bands, and also it is thought that these may cause intrauterine amputations,

Fig 741—*a*, Congenital web fingers, *b* correction obtained by turning a square U shaped flap from the dorsum between the fingers into the proper level on the palmar surface and grafting the defects resulting from separating the fingers, *c* and *d*, diagram of the flaps used. An inverted T is opened on the palmar side and an inverted square U on the dorsal side; the fingers are then entirely separated and the defects covered with thick-split skin grafts. Both sides of one finger are never operated on at one time, as recommended by Kanavel, because of the chance of necrosis from loss of both arteries.

with a free skin graft, rather than, as has been the more common custom, make a number of small local excisions (Fig 740).

Web Fingers.—Web fingers are perhaps the most frequent congenital deformity for which correction is sought. No actual cause is known, but it is thought that if the correction is accomplished fairly early in life, the hand has the best chance to develop (Fig 741). The same operative procedure

but this theory has not had a final solution. The repair of these defects is usually accomplished by careful dissection of one half to three fourths of the complete circumference and then closing the flaps together by making appropriate incisions into them that will allow two or more small flaps to be brought across from one edge into the other.

Deformity or loss of the pad of a finger tip usually results from the placing of an

incision through the pad when a felon is drained and may be so painful or annoying that restoration is required. If skin surface is needed also a pedicle flap can be taken from the thenar or hypothenar areas if the skin covering is satisfactory. Knoch has reported good results in free fat transplantation. Deformity of the eponychium also usually results from linear incisions employed in draining a paronychia. The cor-

ond and third metacarpals to change the action of the second finger into that of the thumb.

Dupuytren's Contracture—Dupuytren's contracture is an idiopathic disease of the palmar fascia in which shortening occurs beginning almost always on the ulnar side of the hand with resultant flexion deformity of the fingers. The involvement may extend up the fingers and over the whole palm

Fig. 47.—a. Abscess of the foot with osteomyelitis of the calcaneus. The area is first cleared, freed of any loose bone fragments and covered with clean granulations. Then a direct pedicle flap is put in place from the opposite thigh. b. Following the flap healed all around the foot. The patient is now able to walk. These forearm flaps retain their original histologic characteristics and must be protected with a rubber sponge pad in the shoe. c. A direct pedicle flap is left in place for three or four weeks. After the flap is set loose the defect on the thigh is covered with thick split grafts.

rection of these is not very satisfactory and care must be taken not to make the deformity worse.

Reconstruction of Fingers—Reconstruction of a finger has been accomplished by transferring a toe, but no very normal looking results have ever been illustrated. A thumb has been built that has proved to be helpful in work by transferring a pedicle flap and putting a free bone graft into it and also by splitting down between the sec-

ond and third metacarpals to change the action of the second finger into that of the thumb and cause the overlying skin to become nodular and attached. Joints may become secondarily deranged. Of many theories of its cause probably the only one of important association is heredity. There is usually no pain but slowly progressive crippling of the hand. The diagnosis is usually simple but mistakes have been made in diagnosing the condition as a contracture of the tendons. Treatment is complete removal of the palmar fascia and if necessary its prolonga-

tion onto the fingers and the application of full thickness skin grafts if closure cannot be easily obtained with the available skin. Extreme care must be taken to prevent injury to the nerves and vessels of the fingers. The papers of Kanavel, Koch and Minson may be taken as standard references.

Restoration of the Skin of the Foot — Restoration of the skin of the foot may often be performed successfully with free skin grafts and in old deformities where there has been loss of skin it may be a necessary procedure as a preliminary to a bone operation. In other instances the sequence of repair may be reversed.

For the restoration of the plantar surface a free skin graft will not suffice over the main bearing points and it is necessary to

apply a pedicle flap—usually from the opposite thigh. This gives an amount of fat that is practically indispensable but even with this flap in place it is necessary to protect the area carefully with a soft sponge rubber pad. This is due to the fact that tissue transplanted from one area to another does not take on the characteristics of the new area. The sole of the foot is different at birth from the tissue of the thigh and even after the passage of years a thigh flap on the foot will still have the consistency of normal thigh tissue. Transplants in other parts of the body do preserve their original histological characteristics.

LOUIS T. BYARS

XXXVII ROENTGENOLOGY

DIAGNOSTIC AND THERAPEUTIC ROENTGENOLOGY IN SURGERY

The employment of the x ray as a diagnostic means has become an essential part of the examination of a large proportion of surgical lesions. Few surgical interventions are now elected except in emergencies without first undertaking some form of roentgenologic study of the patient.

General Considerations.—The roentgen images are only shadowgraphs recording the varying opacities through which the x ray passes, and they are subject to the possibility of numerous incorrect interpretations because of the fact that they are shadows. For successful interpretation it is necessary to become familiar with the roentgenologic aspects of normal structures to understand the technique of roentgenographic and fluoroscopic study, to refrain from making a diagnosis until everything possible in the way of roentgen study has been accomplished to avoid expressing any opinion from films which are not satisfactory and to recognize the limitations as well as the possibilities of roentgenographic investigations.

ROENTGEN FINDINGS IN BONE PATHOLOGY

Fracture lines are characterized by sharply cut margins usually with an irregular course which particularly in the skull does not correspond with vascular markings. Epiphyseal lines are often mistaken for fracture. Periosteal proliferation along interosseous membranes and along intermuscular septa must not be mistaken for true periostitis nor the roughening and slight proliferation which occurs at the attachment of tendons. There is normally roughening on the inferior margins of the pubic bone and on the ischial tuberosity. Calcareous deposits occur extensively in the body outside the bony structures. Solid concretions containing lime are found in the various organs especially the bile passages, urinary tract, appendix and salivary ducts and in certain

cases. Cancellous bones sometimes exhibit small round areas of condensation and transverse lines along the medullary canal toward the ends of the long bones, the result of disturbances of growth.

The various anatomical variations which occur in bony structures must all be taken into account. Suture lines vary greatly and anomalous suture lines occasionally are seen. The facial sinuses and the mastoids vary from complete absence to very great size. Extra ribs and vertebral bodies or parts of bodies may be present or ribs may be absent or fused. Various accessory bones are present in the carpus and tarsus and these are often divided or tripartite. One sees cases of partial or complete absence of long bones or supernumerary bones especially extra fingers or toes.

Fractures and Dislocations.—A roentgenographic study is indispensable in determining the presence and variety of fractures and the degree of separation, displacement and complications, as well as the result of manipulation in adjusting the fragments. A negative diagnosis of fracture should never be made from the fluoroscopic study alone but the fluoroscope may be used to great advantage in reducing fractures and dislocations. When feasible films made in two positions at right angles are better than stereoscopic films. Some fractures cannot be positively demonstrated by means of ordinary x ray study, for instance certain fractures at the base of the skull but submental vertex projections should show them. During the course of treatment x ray studies show the progress of repair and the proper maintenance of position and approximation of fragments.

It was formerly thought that there were certain fractures in the skull especially basilar fractures which might escape detection on x ray examination but the introduction of the rotating anode tube, high milliamperage technique and the general improvement of diagnostic apparatus have removed most of the difficulties formerly

considered insurmountable. If enough films preferably stereoscopic are made in various projections especially the submental vertex projection it is doubtful if any skull fracture could escape detection.

The roentgen ray study of a fracture should determine the type and definite location of the fracture, the relation of the fragments as to apposition, separation, overlapping, angulation, impaction, etc.

Particularly in the skull difficulties may be encountered in differentiating fracture lines from suture lines, diploetic veins and blood vessel grooves. In fractures of the pelvis the sacrum should always be carefully studied for possible fracture. The epiphyses of the pelvis remain open sometimes until the twenty-fifth year. Vascular channels in the ilium occasionally resemble a fracture. Rib fractures may be overlooked even with the most satisfactory technique unless multiple films are exposed. Fractures of the costal cartilage may escape detection unless the cartilage is calcified. In every injury to the wrist or hand the carpal bones should be carefully scrutinized lest carpal fractures be overlooked. In all injuries of the ankle the entire length of the fibula should be explored. In trauma of the knee it is not possible immediately to demonstrate injuries to cartilage such as dislocated or fractured semilunar cartilage unless a small fragment of bone has accompanied the displaced cartilage but some months after the injury when calcification has occurred evidence of old damage to the cartilage may be recognized. In fractures of the hip joint the entire line of fracture is not always demonstrable and unless several films are made the extent of the fracture may be overlooked. In intracapsular fractures of the femoral neck the formation of visible callus is slow or it may not appear at all. A greenstick fracture overlooked at the first examination may become demonstrable later because of the formation of callus.

Interstitial emphysema due to the development of gas phlegmon is occasionally observed. Roentgen films furnish the earliest possible evidence of such a condition and it should be looked for in every wound where gas infection is a possibility. Gaseous infiltration into the soft parts emphasizes the

contours of muscular bundles. X-ray study in gas gangrene permits determination of the depth and outer limits achieved by the infection with precision not possible by clinical examination. Putrid abscesses may be recognized sometimes. X-ray treatment is clearly indicated in cases of gas infection.

Careful search should be made before as well as after the reduction of a dislocation to avoid overlooking associated fractures. Epiphyseal dislocations usually involve a fragment of the contiguous shaft. Separation of the tibial tubercle with thickening and irregularity of the epiphyseal lines (Osgood-Schlatter's disease) is sometimes difficult to differentiate from the normal tibial tubercle which may appear in two or three parts with more or less ragged contours. The same remarks apply to the epiphysis of the os carles.

Infections of Bone—Normal bones are characterized roentgenographically by smooth regular outlines, homogeneous cortex and uniform consistency of the cancellous structures although the cortical thickness and the texture of the spongy bone may vary considerably in different persons.

Pathologic lesions of bones are manifested by alterations in size, outline and density. It is always important to associate the clinical history with the roentgen findings. In interpreting the roentgenographic observations in bone one should note involvement of the medulla or cortex, associated disease in the soft parts, whether the lesion is single or multiple, whether it invades the epiphysis or the joint or is confined to the shaft, whether it involves neighboring bone and whether it is destructive or productive or both.

Increase in the size of bones occurs in cases of osteomyelitis, tumors, simple cyst, fibrocystic disease, Paget's disease and syphilis. Reduction in the size of bone follows trophic disturbance, paralysis and disuse from any cause. Periosteal deposits, callus formation and bone tumors alter the outline of bones. Porosity (or the diminished density) follows disuse, infection or atrophy due to destruction from tumor growth, especially metastatic malignant growths, cystic disease or any one of a series of osteolytic lesions under which may be named bone cysts, osteolytic sarcoma, Brodie's abscess, giant cell tumor, chondroma, metastatic disease, rick-

ets fragilitas ossium multiple myeloma osteomalacia etc Among the osteoplastic bone lesions are exostoses osteogenic sarcoma Ewings sarcoma Graws osteitis marble bones scurvy fibrosarcoma myositis ossificans ossifying periostitis osteitis deformans and hypertrophic osteoarthritis Osteomyelitis and tuberculosis as well as syphilis and myxosarcoma may produce both osteolysis and osteoplasia as may also mammary and prostatic carcinoma

Osteomyelitis produces a certain amount of destruction of the medulla and cortex with an extensive periosteal reaction and resulting formation of sequestra and irregular sclerosis of bone It rarely extends beyond the epiphyseal line The process may exist two weeks or more before any changes are revealed in the roentgen aspect of the bone A negative diagnosis of acute osteomyelitis or periostitis should never be given on x ray findings alone When bone infections have become chronic they always give positive roentgenographic signs

Tuberculosis commonly attacks the epiphyses in younger persons and is characterized as a slowly progressive local destructive process without attempt at regeneration It is rarely found in the diaphysis In the early stages the only finding may be an effusion into the affected joint but the neighboring bones soon show rarefaction with characteristic blurring and loss of detail and later areas of destruction In the wrist and hand the rarefaction may be so severe as to reduce the density of the bones to that of soft tissue As the lesion progresses destruction of joint surfaces occurs with resulting ankylosis Tuberculosis sometimes occurs in multiple foci which later fuse as in the head of the humerus Spinal tuberculosis usually involves the intervertebral disks with destruction of the contiguous portion of the vertebral bodies causing collapse and kyphosis A fusiform paravertebral shadow due to the abscess may be the first evidence of spinal tuberculosis

Syphilitic bone disease is a combined osteolytic and osteoplastic process which may affect any bone at any age Usually it is noted as periostitis or as an irregular area of destruction Syphilitic periostitis is usually confined to the diaphysis extending to the epiphyseal line at both ends In the acute

stage there are multiple distinct laminae superimposed on the old cortex with an irregular outline of the free margin In chronic syphilitic periostitis these laminae become compact and as dense as the normal cortex and the contours of the surface of the enlarged bone become smooth This increased cortical thickness gives the appearance of bowing as in saber shin the cortical thickening occurs on the convex side while in cases of rickets it appears on the concave side Some forms of syphilitic periostitis cause a lace work pattern with strands of calcified material running out at right angles to the cortex resembling the sun ray lines of periosteal sarcoma *Gummatous changes* cause irregular areas of rarefaction This is characteristic in the skull where punched out areas may involve both tables In *congenital syphilis* a juxtaepiphyseal lesion occurring in the shaft is the most common x ray finding associated with the formation of new bone along the shaft *Charcot joints* are characterized by intra articular effusion extensive destruction of the articular ends of the bones and a deposit of osseous debris in the dilated synovial sacs

Chronic osteomyelitis may be simulated by a number of diseases such as *actinomycosis* *Madura foot* *coccinococcus* and *coccidioidal disease* *Coccidiosis* is most common in the bones of the extremity and when it occurs near a joint it resembles tuberculosis *Leprosy* *yaws* and *phosphorus poisoning* all simulate osteomyelitis in the roentgenogram

Bone Tumors—In differentiating *benign* and *malignant bone tumors* it may be said that when the contour of the shadow cast by an osseous tumor is unbroken with few exceptions the lesion is benign A sudden break in the contour of the shadow of a bone speaks for malignancy When invasion of surrounding tissue has taken place lack of definite demarcation of the invading portion of the tumor emphatically suggests malignant lesion whereas if the invading portion continues its definite demarcation this encapsulation indicates a benign lesion Again with few exceptions defects in flat bone even large ones if characterized by smooth definitely outlined margins indicate a benign lesion whereas the malignant lesions are usually marked by indefinite or irregular serrated borders

Even the nature of benign tumors may sometimes be recognized from the roentgenographic characteristics by taking into account the resistance to the rays offered by the various tissues. Cartilage is practically invisible, fibrous tissues cast a certain amount of shadow and bone causes a dense shadow. Many tumors consist of combinations of these tissues and their nature may be estimated according to their radiolucency.

Giant cell tumors, Ewing's tumors (sarcoma) and myeloma are conspicuous exceptions to the general rules for malignant and benign lesions.

Giant cell tumor appears as a single central lesion near the epiphysis of a long bone, tending to grow in all directions but sometimes showing the greatest growth along the path of least resistance, the medullary canal. The cortical bone bulges but rarely breaks and no invasion of soft tissue occurs except where a fracture has occurred. The lesion causes widening of the bone, presenting a lobulated outline divided by many trabeculations and readily invades the epiphysis in contrast to osteogenic sarcoma.

Myeloma a highly malignant lesion follows none of the above rules. The shaft of ribs and long bones may be expanded without a break in contour and without invasion of neighboring tissue. There are multiple round or oval defects, the size of a peanut or hazelnut punched out in appearance, having a predilection for rib, sternum, thoracic and lumbar spine and pelvic bones.

Ewing's sarcoma (endothelial myeloma of bone) is characterized by a diffuse infiltration with resulting widening and increased density of the cortex and an elliptical symmetrical expansion of the shaft near the middle of long bones. New bone formation predominates, giving rise usually to parallel (onion skin) but sometimes radiating spicules. Later both cortical and medullary destructive changes are seen. Invasion of the soft tissues by this neoplasm results in a shadow less definitely encapsulated than that cast by most benign tumors and yet not so promiscuously invasive as osteogenic sarcoma. Ewing's tumors usually respond readily to radiotherapy, though the ultimate prognosis is not so favorable.

Osteogenic tumors may be (a) benign

such as *osteochondroma* and *osteoma* which arise from the cortex by a pedicle, often presenting a cauliflower appearance, never invading or destroying bone. *enchondroma* usually multiple, most frequently found near the ends of the epiphyses in the hands, feet and long bones, simulating giant cell tumor or (b) malignant as in the various types of *osteogenic sarcoma*, subperiosteal and medullary, periosteal, sclerosing telangiectatic and the unclassified types, the latter being entirely osteolytic, showing only loss of substance and no proliferation.

Resembling in roentgenographic characteristics the malignant lesions of bone may be chronic *sclerosing osteitis*, the non-suppurating *osteomyelitis* of Garre, *traumatic* and other types of *osteomyelitis*, *traumatic osteoma*, *subperiosteal hematoma*, *osteitis fibrosa cystica*, *osteitis deformans*, *osteosarcoma* and generalized *xanthomatous* of bone.

Osteochondritis deformans juvenilis (Perthes disease), chronic slowly progressive *osteitis* of the scapular bone (Kienbock's disease), Kuhlér's malacia of the tarsal scaphoid bone in children (as navicularis pedis retardatum) and several other similar chondral lesions are demonstrable with roentgen studies.

Metastatic Tumors—Carcinoma in bone is always metastatic and generally multiple, involving any one or all of the bones. It is not often found in the extremities below the knees or the elbows. Osteolytic forms predominate, producing a moth eaten appearance due to irregular destruction of bone substance with no periosteal reaction and no change in contour unless pathologic fracture occurs. In the osteoplastic form, which is usually secondary to prostatic or mammary carcinoma, there is extensive production of dense bone with coarse mottling due to intermingled areas of rarefaction and condensation and sometimes with enlargement of the bones suggestive of *osteitis deformans*. Metastases from hypernephroma have a predilection for bones. Malignant disease of the testicle and of the bladder rarely metastasizes to bone. Approximately 6 per cent of uterine and 3 per cent of ovarian malignant tumors cause skeletal metastases. Bone metastases are encountered in about 1 per cent of the cases of malignant diseases of the digestive tube and in about 15 per cent

crises of malignant disease of the lung. Lymphosarcoma may metastasize to bone and osteogenic sarcoma may present multicentric growths. Pathologic fractures are often discovered in metastatic bone lesions.

The Head and the Skull.—By the injection of air into the spinal canal (encephalography) and the injection of air into the ventricles through small trephine openings in the parieto-occipital regions (ventriculography) new aid is rendered in the demonstration of intracranial tumors and post-inflammatory or post-hemorrhagic cicatricial lesions which distort the ventricles or obliterate the subarachnoid spaces. In the spinal canal the injection of air or opaque media permits the localization of spinal cord tumors and other crises of compression of the cord. A brain tumor sometimes causes changes in the skull which are recognizable in simple films without the aid of ventriculography or encephalography. Calcification in the mass itself is rare but it occurs just often enough to be tantalizing. Localized erosions, dilated vascular channels in the inner table of the skull, irregular osteoporosis when lesions are situated in or near the ear, antrum, new bone formation in the dura and displacement of a calcified pineal gland are other signs seen in crises of brain tumors. Growth in the cerebellopontine angle may erode and push forward the posterior clinoid process.

Deformity of the *sella turcica* is also seen in crises of generalized increase of intracranial pressure and intrasellar tumors. In *acromegaly* there is enlargement of the sinuses, elongation of the mandible, a general increase in size of the bones of the hands and feet and coarsening of the texture of spongy bone in general. In addition to the local destructive changes consisting of spherical enlargement and thinning of the sella, sometimes with perforation of the floor and altered contours of the posterior clinoid process.

Premature closure of the cranial sutures early in life causes the striking picture of tower skull or turret head (*oxycephaly*) showing an abnormally high and broad skull with numerous crescentic markings in the inner table corresponding to convolitional pressure atrophy (unicus bones digitorum).

Hydrocephalus enlarges and thins the

vault of the skull, exaggerates the convolutional impressions, sometimes separates the sutures and flattens the sella. Ventriculography shows remarkable ventricular dilatation and reduction of the thickness of the cortex.

Roentgenography of the accessory sinuses constitutes a subject which cannot be dealt with in a paragraph. In roentgenograms made for the sinuses one may recognize thickening of the lining membranes by a generalized uniform haziness, tumors such as osteoma or polypoid growth, malignant disease, empyema and other lesions.

Acute *mastoiditis* causes general haziness of the affected cells with blurring of their marginal contours. More advanced cases show destruction of cells and loss of detailed outlines with an indefinite area of increased density. Comparison of the two sides is helpful. Anomalies are usually bilateral. Chronic crises show more or less absence of cells and a certain amount of sclerosis.

Dental film studies supplemented when necessary by extraoral roentgenograms of the lower jaw aid in the detection of dental foci of infection. The following are the principal lesions shown in relation to the teeth: apical periodontitis, granuloma, apical chronic abscess with scar bone, wall off abscess or erosion of the tip of the root, root cyst, osteomyelitis, necrosis and sequestrum formation, pathologic change in the pulp and periodontal disease.

Salivary calculi cast dense oval or rounded shadows in the position of the salivary glands or their ducts. Much technical ingenuity is required to demonstrate such calculi. Sialography by the introduction of opaque oil through a cannula into the duct of the affected salivary gland is often very useful in diagnosis.

The *jaw* is subject to the same diseases seen in bone elsewhere. Special mention should be made of the following conditions:

a. *Root cysts* appear as single or multiple rounded areas of rarefaction. They are well demarcated, enclose the roots of one or more teeth and show little or no trabeculation.

b. *Dentigerous cysts* are similar but since they develop from a buried tooth germ they usually contain teeth.

c. An *odontoma* is seen as a dense mass of dental tissues attached to a tooth or com-

posed of a compact fused mass of several teeth.

d. An *adamantinoma* forms a large slowly developing mass containing multiple small cysts sometimes calcified which expels the alveolar process. These growths do not metastasize. Occasionally there is a solid form of this tumor.

LOCALIZATION OF FOREIGN BODIES AND REDUCTION OF FRACTURES

Localization of foreign bodies under x-ray examination has been brought to a high degree of perfection through the immense practice gained during World War I. When the foreign body is large enough to be seen on the screen fluoroscopic localization marking localizing points on the skin with indelible ink gives the most prompt and satisfactory service to the surgeon. Numerous localization methods are described in the literature,¹ but space here will not permit a description of them. Film records in two or more directions, stereoscopic films and films made after the introduction of needles into the soft tissues in the vicinity of the foreign body and left in place during the operation as well as during the x-ray study are all means to the command of every hospital. Simple fluoroscopic methods of accurate localization which may be employed with any standard type of fluoroscope have been described by Gilbert and Harkness² and the method provided with the U. S. Army table unit has been set forth by de Lamerie.³

Utilization of the fluoroscopic screen during extraction of opaque foreign bodies is not sufficiently appreciated by American surgeons, especially the younger men who did not have an opportunity for war service. One of the operating staff must use dark glasses to protect his eyes from light or else the preliminary exposure of the field must be obtained with a red light to preserve the surgeon's accommodation. The operation must be performed in the x-ray fluoroscopic room on the standard fluoroscopic table, or a portable x-ray apparatus (preferably a shock-proof instrument) should be taken to the operating room and the screen observations made by one of the doctors using a bonnet type of fluoroscope. The x-ray apparatus in use should be calibrated under

the conditions employed in the actual operation as to accurately measured target film distance, milliamperes, voltage and the output in roentgens per minute and by means of an integrating time clock careful watch should be maintained so that no skin area receives more than 300 roentgens. A foot switch should be employed and the current turned on only after the surgeon's eyes have focused on the screen, not a second of screen illumination should be wasted. The opening in the diaphragm should be as small as possible and suitably long instruments used so that the operator's fingers are never exposed. Specially devised forceps for the extraction of foreign bodies are available. Removal of a foreign body is often of minor consequence in the treatment of war wounds.

The reduction of fractures under fluoroscopic control involves the principles just described. No surgeon should resort to fluoroscopic control of reduction manipulation unless it is quite impossible to do without it; otherwise he will sooner or later suffer damage from repeated exposures, however brief they may be. When this aid is required the observations should be made as brief as possible and a total skin dosage of 300 roentgens in an individual case should not be exceeded without a time interval of three weeks. Here too the field of screen illumination should be as small as is compatible with expeditious work. An aluminum filter of from 0.5 to 1 mm. thickness is absolutely necessary for safe fluoroscopic work.

THE THORAX

Roentgen interpretation of intrathoracic pathologic states must depend fundamentally on gross alterations of the normal shadows which may be recognized in the films or screen image. The large air content of the lungs enhances the visibility of the pathologic process. The screen study is of more value in the study of viscera in motion for noting deviations of organs or accumulations of fluid on change of posture and in the various respiratory phases and in the differentiation between transmitted and expansile pulsation. Films record finer details than can be recognized fluoroscopically.

The bones of the thorax are subject to the same diseases as skeletal structures elsewhere. Soft tissue emphysema may accom-

pain, the fracture of a rib or other injuries in which the lung is punctured.

The central shadow of the chest includes the pericardium and its contents and the great vessels, the thyroid if it extends into the thorax, the thymus when present and the root of the lungs. An *enlarged thymus* sometimes resembles a small heart capping the normal cardiovascular shadow, sometimes it presents a roughly quadrangular shadow. A *retrosternal extension of the thyroid* is usually broad in its upper portion, narrowing to the point of disappearance over the shadow of the great vessels; it frequently results in tracheal compression or deviation. Enlargements of the *tracheobronchial and other neighboring glands*, generally due to Hodgkin's disease, tuberculosis or metastasis from malignant disease elsewhere in the body, present sharply defined irregular or lobulated shadows, often bilateral without intrinsic pulsation, although the larger masses transmit pulsations from the heart or aorta. *Hodgkin's disease* is usually accompanied by glandular enlargements elsewhere. Radiation therapy supplies a therapeutic test, since under irradiation the glands rapidly diminish in size or disappear. *Lymphosarcoma* closely resembles Hodgkin's disease. *Malignant mediastinal tumors* show more irregularity of outline, tending to invade the surrounding tissues rather than to displace them. The presence or absence of pulsation has not been of much help in making a differential diagnosis. Some aneurysms do not pulsate, transmitted and expansile pulsations are not easily differentiated.

The various *valvular lesions of the heart*, when they have altered the size of the cardiac chambers, show more or less characteristic x-ray evidence which contributes to the accuracy of the clinical diagnosis. *Cardiac aneurysms* occur occasionally, usually in the ventricular region as a sequel of coronary infarcts and should be recognized. Calcifications of the cardiac valves are more easily discovered on the screen than they are on roentgenograms.

Syphilis affects especially the root of the aorta, the mouths of the coronary arteries and the aortic cusps; the aortic shadow bulges markedly to the right, pulsates prominently and is definitely increased in diameter.

In *arteriosclerosis* the heart may show no change or may be enlarged to the left and the aortic shadow is increased toward the left with marked prominence of the aortic knob, sometimes showing dense calcareous plaques. The roentgen findings are often complicated by broken compensation with resulting pulmonary circulatory stasis and evidence of small fluid accumulations in one or both costophrenic angles.

In *pericardial effusion* the heart shadow is triangular with the apex pointing toward the region of the great vessels, giving a water bottle shape to the heart shadow, especially when the patient is in an upright position. Cardiac pulsation is greatly diminished or absent when it is distinguishable; the impulse is more or less general over the entire left border without distinction between the muscular and ventricular pulsation. Amounts of pericardial effusion even up to 200 cc. may escape observation. The differential diagnosis between cardiac dilatation and pericardial effusion depends chiefly on the presence or absence of the altered shape of the heart shadow when the patient's position is changed.

Aneurysms of the ascending aorta show bulging of the aortic shadow to the right; those of the arch appear higher up and to the left and those of the descending portion to the left, more or less superimposed on the cardiac shadow. The position of the aneurysmal sac is of the greatest importance. Disturbances of the aorta are aneurysmal in character but involve the entire thoracic aorta. Tortuosity of the aorta may simulate diffuse dilatation or aneurysm. The paravertebral fusiform shadow due to the abscess of Pott's disease should not be confused with aneurysm.

Mediastinal pleurisy or abscess is best distinguished by lateral study of the chest. The shape of the shadow does not change with respiration or with the position of the patient; indeed, the movements of the diaphragm are limited or paradoxical.

Hernia of the diaphragm shows roentgenologically as a cyst like mass above the diaphragm, usually the left containing air or fluid or both. The nature of the lesion is studied by an opaque meal and at times by an opaque enema. By using every device of fluoroscopy in various positions and at vari-

ous angles it will be possible to differentiate a hernia through the esophageal hiatus from a hernia through an acquired or congenital rent in the diaphragm and to determine the approximate size and position of the rent as well as to recognize eventration of the diaphragm.

Subphrenic abscess shows elevation and limitation of movement of the diaphragm on the affected side and later secondary supraphrenic pulmonary and pleural involvement. In perhaps a third of the cases the abscess cavity contains gas which causes a fluid level to form that can be determined by a study made in the erect or lateral position. A subphrenic abscess may be simulated by a consolidated lung just above the diaphragm and by an abscess of the liver or a subhepatic or perinephritic abscess.

Pulmonary tuberculosis is rarely present without sufficient gross change in the tissues to produce shadows on the roentgenograms. This is more true of adults while for infants peribronchial tuberculosis may entirely escape roentgenologic detection. The interpretation should be conservative. Undoubtedly in many cases an incorrect diagnosis of pulmonary tuberculosis has been made because too much pathologic evidence was read into x-ray films of the chest. Any operation on the chest looking to the cure of pulmonary tuberculosis should be rigidly controlled at intervals by x-ray observations.

Postoperative pulmonary complications should be more frequently controlled by bedside x-ray studies. *Lobar pneumonia* is characterized by clearly defined areas of homogeneous increased density which partially or completely occupy the position of pulmonary lobes. There is at first a slight veil-like shadow in the central lung field associated with an accentuated peribronchial marking. The veiling increases in density as the exudative process advances. As resolution takes place there remains a distinct mottling which gives place to thickened bronchial markings or large glands. Pneumonic shadows are less dense than the shadow of the fluid fluid in fair amount displaces the heart and other mediastinal structures to the opposite side whereas lobar pneumonia causes no displacement. Respiratory motion and diaphragmatic excursion are reduced in lobar pneumonia.

In *bronchopneumonia* the relation of the single or multiple shadows of increased density to the larger bronchi is easily recognized. They rarely reach the pleura and they completely obliterate the lung markings only rarely. There is rarely any interference with the excursion of the diaphragm. Pulmonary circulatory stasis may simulate bronchopneumonia. An atypical bronchopneumonia not due to a pneumococcus and usually without leukocytosis has been generally accepted as *virus pneumonia*.

Infects of the lung show sharply defined areas of increased density, single or multiple without displacement of mediastinal structures or interference with the diaphragm. They are usually triangular in shape with the apex of the triangle pointing toward the root of the lung.

Pulmonary abscess usually follows acute infection, aspiration of infected material (as at operation) or the inhalation of foreign bodies. Lung abscesses are usually single occurring more often at the bases especially the right and giving rise to irregular shadow areas which are denser at the center and fade out into the normal lung tissue. Cavity formation supervenes as necrosis occurs in the center of the density. When air is present in the cavity the fluid assumes a level which shifts according to the position of the patient. The associated bronchial markings are coarser than normal and the roots of the lungs are usually enlarged. Information should be sought concerning the presence or absence of an adherent pleura and the distance from the abscess to the nearest point of external approach. Tuberculous cavities are usually empty while ordinary abscess cavities usually contain some fluid. Confusing lesions are those of tuberculosis, bronchopneumonia and bronchiectasis. Multiple abscess may simulate metastatic malignant disease or bronchopneumonia.

Pleural effusions collect in the most dependent part of the thorax causing a very dense shadow which obscures the ribs and the diaphragm. In simple hydrothorax the upper border of the shadow curves upward toward the chest wall in the axillary line. In hydropneumothorax there is a fluid level which changes according to the position of the patient. When the effusion is extensive

displacement of the mediastinal structures occurs toward the opposite side and there is evidence of compression of the lung. Fluid which develops in bedridden patients sometimes becomes encapsulated and produces a sharply defined shadow along the axillary border. Collections of interlobar pleural fluid may become encapsulated showing better on lateral than on posterior-anterior projection. In cases of unencapsulated pleural effusion without pneumothorax the shape of the shadow changes only sluggishly as the position of the patient is altered. Encapsulated fluid should be carefully localized so as to facilitate accurate surgical approach. The density of the shadow of pleural effusions is the same whether due to pus, serum or blood. Simple serous pleural effusions are rarely encapsulated; encapsulation suggests empyema.

Pneumothorax with the lung partially collapsed and the pleural cavity containing air may occur spontaneously with little or no evidence of pulmonary disease. The lung markings are absent in the pleura outside the contracted lung. If no pleural adhesions are present the lung appears as a lobulated central mass but when adhesions have formed the collapse is incomplete. This is true both in spontaneous and in artificial pneumothorax.

Pleural calcifications cause ragged dense flat or linear shadows corresponding to pleural sites.

Bronchiectasis is characterized by extensive thickening of the lung markings usually along the larger descending branches of the bronchial tree with enlarged root glands and diffuse clouding in the lower portions of the lungs sometimes showing multiple small fluid levels corresponding to the various bronchiectatic cavities. Emphysema may be an associated finding. The introduction of iodized oil into the bronchi reveals the exact location and size of the bronchiectatic cavities.

Foreign bodies cause a surrounding area of increased density as a result of localized pneumonia, the formation of an abscess or the collapse of one or more lobes because of bronchiostenosis. Sometimes the foreign body acts as a ball valve permitting air to pass into but not out of one or more lobes. Opaque foreign bodies are easily visualized

and localized but the presence of a non-opaque foreign body must be deduced from the fact that air can enter freely but its expulsion may be obstructed. During expiration the involved lobe shows emphysema with increased translucency to the rays; the diaphragm on the affected side is depressed and flattened and the heart may be displaced toward the opposite side. When the bronchus is completely obstructed the air in that portion of the lung is soon absorbed and atelectasis occurs resulting in density of the involved lobe, retraction of the thoracic cage, narrowing of the intercostal spaces, elevation of the diaphragm and retraction of the mediastinal contents toward the involved side. Such a condition of atelectasis involving all or part of a lung may occur during or after operation following the aspiration of a clot of mucus or other similar material. If the foreign body persists or if it consists of infected material inflammatory changes take place which resemble bronchopneumonia, consolidation, local degeneration and abscess may follow. The majority of aspirated foreign bodies occupy the right bronchus unless they are too large in which case they lodge in the trachea. A foreign body may lodge in one of the bronchi of the upper lobe if inhaled while the patient is horizontal. Fluoroscopy, especially biplane, may aid materially in the bronchoscopic procedures for removal of foreign bodies.

Pleural malignant disease is not easily diagnosed from the x-ray findings alone. It may be masked by the accompanying effusion. In suspected cases withdrawal of the fluid should be followed immediately by roentgen study at which a diffuse thickening may be the only x-ray evidence.

Primary pulmonary malignant disease is usually unilateral. The nodular type presents peripheral dense rounded masses sometimes with the formation of an irregular cavity. The infiltrated type follows the larger branches of the lung tree sooner or later advancing into the parenchymal tissue. Partial collapse may take place with the usual accompaniments of atelectasis; pleural effusion is seen early. Pulmonary malignant disease especially when primary is altogether too often unsuspected and overlooked.

Metastatic malignant disease is seen most commonly as multiple usually rounded

sharply defined densities of variable size scattered throughout both lungs. Sometimes pulmonary metastatic malignant disease causes a fine mottling diffuse throughout both lungs which is larger, more dense, and more sharply defined than in miliary tuberculosis. Another type of metastasis begins in the bronchi with the development of large masses at the roots of the lungs and with effusion at one or both bases.

Hydatid cysts of the lung occur most often in the bases usually a unilateral single lesion but sometimes bilateral and multiple. There is often a shell of calcareous material surrounding the cyst. If rupture has occurred inflammatory reactions follow resembling lung abscess.

THE DIGESTIVE ORGANS

Many gastrointestinal surgical lesions are roentgenologically recognizable because of some alteration of the normal morphology or function. It is therefore a prime essential that the roentgenologist should be thoroughly familiar with the fluoroscopic and roentgenographic anatomical and physiologic aspects of the normal digestive tract, a knowledge which can be gained only by abundant experience. Naturally the lumen of the digestive tract must be visualized either orally or rectally by the administration of some contrast substance usually barium sulfate sometimes supplemented by air inflation.

Esophagus—Esophageal diverticula show an ovoid sac of greater or lesser size usually located to the left and posteriorly in the upper esophagus though epiphrenic diverticula do occur. The opaque medium passes readily down the practically unobstructed esophagus alongside the diverticular sac. Regurgitation and aspiration of the barium may occur with visualization of the bronchial tree. A congenitally short esophagus with a portion of the stomach above the diaphragm may be confused with hernia of the stomach through the esophageal hiatus or a supraphrenic diverticulum.

Esophageal carcinoma is characterized by tortuous or irregular contours of the stenosed lumen with some dilatation above the stenosis usually less marked than in cases of benign obstruction. Antiperistalsis is often seen in cases of obstruction. A rough or indented

filling defect of the esophageal lumen proportionate to the size of the growth may be demonstrated especially with the patient in the horizontal position.

Cardiospasm is marked by signs of obstruction near the cardia the smooth symmetrical termination of the lower end of the dilated esophageal shadow showing a blunt or regularly conical contour as contrasted with the usual dentated aspect seen in carcinoma. The dilatation is often extreme and the contours of the upper part of the esophagus are marked by contraction waves often with antiperistalsis or spasmodic contractions.

Spasm may occur anywhere in the esophagus as a reflex result of early carcinoma, be cause of gastric irritations or because of the presence of foreign bodies. Non opaque foreign bodies may be recognized sometimes by fluoroscopic search for a point of temporary or lasting obstruction of barium.

Aside from the evidence of obstruction cicatricial stenoses following healed simple syphilitic or tuberculous ulcer trauma or from swallowing caustic liquids do not give especially characteristic x-ray findings. The differential diagnosis must depend on the history. There is usually a rounded symmetrical smooth termination to the dilated esophageal shadow a thin stream of opaque material trickling through the stenosis.

Esophageal varices are sometimes shown by using a barium sulfate-glycerin mixture or an aqueous solution of thorium dioxide (umbrathor).

Stomach—Organic intragastric lesions are betrayed by a derangement of the normal symmetry of the gastric rugae by changes in size, mobility, motility, secretion or peristalsis and by persistent deformity of the laminar contour but such deformities as well as alterations of motility, tone and peristalsis are sometimes materially confused by spasm. Indeed spasm is chiefly accountable for some of the characteristic changes in form such as the spastic hourglass stomach in a case of ulcer and much of the deformity of the duodenal bulb in a case of duodenal ulcer. Spastic indentation of the greater curvature at the lesion's level diffuse spastic distortion or reflex pyloric spasm may occur in gastric ulcer. When reflex spasm is suspected an antispasmodic should

be administered to full physiologic effect. Spasm of any sort will disappear under the influence of a general anesthesia.

Distinct roentgenologic signs are present in 95 per cent of the cases of *gastric cancers* and include filling defects corresponding more or less to the size and shape of the tumor, alterations of pyloric function usually with gaping of the opening but sometimes with obstruction when the lesion is near the pylorus, absence of peristalsis in the area of the growth with weak or exaggerated peristalsis and at times antiperistalsis or irregular peristalsis depending on the nearness of the lesion to the pylorus, rapid and early emptying in non-obstructive cases and usually a delay in cases with obstruction, lessened flexibility and mobility of the gastric wall and other less important signs. The type of malignant growth, colloid fungous or scirrhous is sometimes indicated by the character of the filling defect. Most 'leather bottle' stomachs are due to the diffuse infiltrative scirrhous type of carcinoma. The operability of a gastric carcinoma may often be estimated with great accuracy from the roentgen examination.

In gastric syphilis the roentgen findings are usually not characteristic and pathognomonic but taken together with the other laboratory and clinical evidence they should lead to a high percentage of correct diagnosis. A gastric filling defect usually without a palpable mass, an irregular concentric contraction producing an hourglass stomach and a discrepancy between the extent of the organic gastric involvement and the history and relatively good general condition of the patient.

Other benign tumor producing lesions of the stomach including myomas, fibromas, often polypoid and adenomas, and occasionally lipomas, cause filling defects which simulate carcinoma but lack the dentated contours. Tuberculosis of the stomach is very rare as are angiomata, dermoid cyst and generalized gastric polypus.

Of *gastric ulcers* 90 per cent should be demonstrable at roentgen examination. It may be impossible to demonstrate simple ulcers since they are small, shallow and often slit like minute ulcerations, especially when not accompanied by indirect signs, such as spastic incisures or retention. Penetrating ulcers show a crater extending out

from the gastric lumen, sometimes causing the formation of diverticula or accessory pockets which in the erect position may show an air bubble and hourglass formation. Indirect signs include various spastic manifestations such as the incisure, hourglass, spastic stomach or diffuse gastrosphincter spasm, diminished tonus, delayed emptying, weakened peristalsis and a point of tenderness corresponding to the site of the ulcer unless the ulcer occurs in the pyloric zone in which event the symptoms will resemble those of duodenal ulcer. An hourglass stomach is sometimes simulated by a 'crescentic stomach'.

Various *foreign bodies* may be found in the stomach, the most interesting being the non opaque hair balls and phytobezors. *Diverticular sacs* are occasionally found in the stomach usually near the cardia where they may be mistaken for ulcers. *Diaphragmatic hernia* is fairly common either through the esophageal orifice (*hiatus hernia*) or through an actual rent in the diaphragm. In *congenital pyloric stenosis* roentgen studies may demonstrate the degree of pyloric stenosis, the time needed for gastric evacuation and the presence or absence of dilatation and should aid in differentiation from pylorospasm.

Following operation roentgen study is indicated whenever the results are not satisfactory, especially after gastroenterostomy. Jejunal and gastrojejunal ulcers may show any one or more of the following signs: a persistent neck representing the crater of the ulcer, deformity about the stoma, diminished patency of the stoma with gastric dilatation and gastric retention, deformity and narrowing of the afferent loop, gastric hyperperistalsis, duodenal dilatation and the coincidence of a point of pressure pain with the stoma.

Duodenum and Small Intestine—The chief duodenal lesions demonstrable on x ray study are listed below together with the chief roentgen signs.

In *duodenal ulcer* distortion of the duodenal bulb almost always occurs, often quite out of proportion to the organic changes found at operation. The bulbular deformity is chiefly the result of intrinsic spasm, supplemented by edema and inflammatory infiltration. Persistent resemblance of the bulbular

outline to a pine tree or a bit of branched coral the deformity involving one or both lateral borders almost always indicates the presence of a duodenal ulcer. Other deformities involve the basal border of the bulb others are of the niche type still others are of the incisura type perhaps with an hour glass duodenum. Accessory pockets or sacculations are also seen following invasion of the ulcer into the periduodenal tissues. In a very large percentage of cases a constant deformity of the duodenal bulb is pathognomonic of duodenal ulcer but such deformity may also result from periduodenal or pericholecystic adhesions or from cancer of the duodenum. Deformity of the bulb may also occur from extrinsic spasm as from gall bladder or pancreatic disease.

Obstructing duodenal ulcer causes gastric stasis and hypertrophy with gastric dilatation. In such cases hyperperistalsis alternates with periods of almost complete absence of peristalsis. Hypertonicity, hyperperistalsis and hypermotility constitute the triad of important indirect signs of non obstructing duodenal ulcer. Sometimes hypermotility is noted during the early minutes or first half hour of digestion followed by delayed emptying as pyloric spasm and hyperacidity develop.

Duverticula of the duodenum or upper small intestine are chiefly non symptomatic although occasionally one is found with diverticulitis or a periduodenal inflammation response. In very few cases of Meckel's diverticulum has the sac been demonstrated roentgenologically though the obstructive complications may be recognized if they exist.

A special technic with umbrathor or a similar preparation for visualizing the rugae and the use of compression and multiple films are required to demonstrate carcinoma or other tumors of the duodenum but with this technic the filling defect caused by the tumor even when small may be shown. Encroachment of periduodenal cancer as of the pancreas or peritoneum may also be shown by serial studies with careful compression technic.

Obstruction of the small intestine from various causes may be shown by means of x ray study after the ingestion of an opaque substance (1 ounce of barium sulfate sus-

pended in glucose solution or a dilution of umbrathor) indeed in acute cases the obstruction and its approximate site may often be determined by the disposition of gas and the level of fluid as shown by a simple film of the abdomen. Carcinoma of the small intestine has recently come well within the field of successful roentgen diagnosis but its recognition demands patient frequent study at half hour intervals with compression technic once the probable site of the lesion has been made out. The addition of intestinal intubation with the administration of opaque material through this tube when it has reached the approximate site of the lesion still further adds to the prospect of success. The x ray aspect of a small intestinal obstruction may be simulated by obstructive lesions of the colon even though occurring as far over as the left third of the transverse colon. *Tuberculosis of the terminal ileum* is characterized by extreme irritability or inhospitability so that the affected segment refuses to retain its opaque content. The cecum often shares this irritability giving rise to Stierli's sign. In later stages hypertrophic lesions develop with obstruction. *Regional ileitis* is often multiple involving several segments of the ileum usually the terminal portion distal to each dilated segment the narrow ileac lumen is recognized by the string sign.

Colon—The colon varies greatly as to length diameter disposition in the abdomen and mobility. Redundancies are common and not necessarily pathologic especially in the sigmoid flexure. Positions and configurations vary from hour to hour as seen at successive examinations. The haustral contractions especially emphasized in the transverse and descending portions of the large intestine are seen prominently also in the cecum and ascending colon. They are more pronounced when the colon is visualized by a barium meal than by an opaque enema but if the enema is retained for a short time the haustral markings usually become quite prominent. After an opaque meal the haustral markings disappear momentarily at the time of spontaneous mass or transport movements. Severe grades of colitis such as may be present in tuberculosis chronic ulcerative colitis and various forms of dysentery are character-

ized by the persistent absence of the haustral markings and by hypermotility. Displacement of the colon may sometimes give a clue as to the identity of intra abdominal or retroperitoneal tumors *e g* splenic tumors displace the left flexure of the colon downward whereas renal tumors usually elevate it and spread apart its loops.

The concentric or unilateral filling defect due to *carcinoma* of the colon is irregular and constant and maintains its site in the colon regardless of manipulations during palpation. The combination of an opaque enema and injection of air may reveal details concerning the exact extent of the lesion that are not recognizable with the simple opaque enema technique. The filling defect in cases of colonic carcinoma may be simulated by gas or fecal matter spasm, an insufficient quantity of the opaque enema, pressure of extrinsic tumors neighboring viscera or bony parts, adhesions and especially such gross lesions as tuberculosis and diverticulitis of the colon. The inflammatory thickening attending diverticulitis may produce both a filling defect and obstruction and unless at least a few of the diverticular sacculations are discovered it may be impossible to make a differential diagnosis. The filling defects due to tuberculosis usually involve the proximal colon often with the terminal ileum and there is a surprising lack of palpable mass in consideration of the apparent size and extent of the lesion. Colonic carcinoma may be simulated by pericecal abscess associated with appendicitis and by actinomycotic polypoid syphilitic and non specific granulomatous lesions.

The early stages of *diverticulitis* may be recognized by mucosal herniations and entero spasm most marked in the sigmoid colon. Symptomless colonic diverticula (diverticulosis) are common when associated with enterospasm abdominal pain (often of great severity) constipation vesical symptoms and in many cases a palpable tumor. The recognition of diverticulitis becomes a matter of importance. Complications such as fistulas perforation peritonitis abscess formation adhesions and superimposed carcinoma may complicate the roentgenologic findings.

In intestinal tuberculosis the chief roent-

gen finding is the filling defect due to the ulcerative and inflammatory process plus the spastic manifestations. The haustral markings are usually absent and hypermotility is of extreme grade unless the process has reached an obstructive stage. *Chronic ulcerative colitis* and *intestinal polyposis* are best studied by the combined opaque enema and the injection of air which may permit the identification of individual ulcers and polypi, especially in stereoscopic films.

The normal appendix receives and evacuates the barium meal when given by mouth within the time necessary for evacuation of the cecum. By opaque enema the appendix may not at first become visualized but if observations are made after a few hours some of the retained opaque enema will find its way into the normal appendix. Roentgen signs of a pathologic appendiceal condition adhesions persistent kinking concretions localized pressure-tender point localized narrowing of the lumen and absence of the appendiceal shadow.

Intestinal *intussusception* should be recognized by the opaque enema which sometimes in acute cases serves to unfold the intussuscepted bowel. Chronic intussusception may cause a large filling defect which is easily confused with carcinoma of the colon. *Congenital idiopathic dilatation* of the colon is easily recognized by the opaque enema and in most cases it is not necessary to administer any opaque material the condition being betrayed by the gas-outlined contours of the dilated segment.

Postoperative *gastrocolic fistulas* and fecal fistulas from other causes such as abscesses or injuries to the intestinal wall are profitably studied with the x-ray after appropriate visualization of the small tract by opaque oil or by the routine barium meal or enema.

Peritoneal Cavity —For a time roentgen study after *artificial pneumoperitoneum* by the introduction of air or gas into the peritoneal cavity was highly recommended as a method of differentiating intra abdominal and retroperitoneal tumors but its popularity has faded until today it is a rarely indicated but nevertheless at times valuable diagnostic aid. This is especially true in countries where hydatid disease is prevalent. Spontaneous pneumoperitoneum may be a

sign of rupture of a hollow viscus as by perforation of an ulcer.

Liver and Gallbladder.—Plain films show the size of the liver and its shape. Gallstones are revealed if they contain lime and rarely does the gallbladder show by calcification of its walls. Attempts to discern the gallbladder shadow on plain films or estimate gallbladder impressions in the duodenal bulb are likely to lead to much error because the duodenum itself may cast an avoid shadow resembling the gallbladder and pressure defects in the duodenal bulb may be made by a lobe of the liver approximating the gallbladder in size and shape. Even if a shadow is cast by the gallbladder, that is not sufficient basis for believing the gallbladder to be pathologic. Shadows suspected of being gallstones should be carefully differentiated from right renal stones by intravenous or retrograde pyelography or by plain roentgenograms made at an oblique projection so as to cast the shadow outside of the shadow of the kidney from calcified mesenteric glands whose shadows are usually multiple and have a resemblance to millerries and from calcifications in the chondral portions of the ribs.

Graham Cole, Copher and Moore in 1923 discovered that it is possible to administer in the late afternoon either intravenously or orally 3 or 4 Gm. of tetraiodophenolphthalein (for *cholecystography*) and show the gallbladder in films made the next morning no food other than carbohydrates being taken meanwhile. The resulting cholecystograms normally show the uniformly dense shadow of the gallbladder which empties within one half to two or three hours after a meal containing fat. Cholesterol gallstones show as defects in the gallbladder shadow somewhat suggestive of vacuoles in an amber unless the cystic duct is blocked in which case no dye enters the gallbladder and "absence of shadow" is noted. When no shadow can be found there is a 90 per cent probability that cholelithic disease is present (75 per cent of absence of shadow cases showing gallstones) and a 10 per cent probability of extracholelithic disease of the biliary tract. Faint or distorted shadows may indicate pericholelithic adhesions and other non-calculous cholelithiasis.

Cholangiography is often useful in study

of the common duct. In cases of biliary fistula a 50 per cent dilution of thorotrast or metopax or up to 25 cc. of thorotrast may be introduced into the fistulous opening so that one can visualize the common duct determine the absence of stones from the duct or the papilla of Vater or exclude other types of common duct obstruction. The retrograde passage of the opaque material into the biliary radicals does not appear to be in any way harmful.

Cholangiography may be performed during operation by injecting the opaque material either into the gallbladder or into the common duct. A film previously placed under the patient is exposed by properly grounded bedside x-ray equipment used in the operating room with special precautions against explosions depending on the method employed.

Visualization of the liver and spleen (*hepatosplenography*) by the intravenous introduction of thorotrast may in rare occasions be indicated especially when it seems important to demonstrate the presence or absence of malignant disease of the liver. Because of possible dangers inherent in the use of thorium dioxide the method must be restricted to cases in which the patients are in the middle or older age groups and to cases in which in the presence of definite malignant disease there is the pertinent question of metastatic involvement.

URINARY TRACT

Probably 99 per cent of all renal and ureteral stones will show on a plain film; a smaller proportion of cystic stones will be found. Many shadows lying along the course of the urinary tract must be differentiated: the principal ones of a very long list being gallstones, calcified mesenteric glands, appendiceal calculi, tuberculous foci in the kidney, calcifications occurring in the pancreas in hematomas or in old abscesses, unabsorbed opaque pills and other foreign bodies in the intestine. Plain films should also demonstrate the contour, size and relative position of the kidneys, the outlines of the psoas muscles and the outline of the bladder. Distortions of the psoas muscles are observed in psoas abscess or in paravertebral tumors of any kind and in perinephric abscess.

ized by the persistent absence of the haustral markings and by hypermotility. Displacement of the colon may sometimes give a clue as to the identity of intra abdominal or retroperitoneal tumors *e g* splenic tumors displace the left flexure of the colon downward whereas renal tumors usually elevate it and spread apart its loops.

The concentric or unilateral filling defect due to *carcinoma* of the colon is irregular and constant and maintains its site in the colon regardless of manipulations during palpation. The combination of an opaque enema and injection of air may reveal details concerning the exact extent of the lesion that are not recognizable with the simple opaque enema technic. The filling defect in cases of colonic carcinoma may be simulated by gas or fecal matter spasm in insufficient quantity of the opaque enema pressure of extrinsic tumors neighboring viscera or bony parts adhesions and especially such gross lesions as tuberculosis and diverticulitis of the colon. The inflammatory thickening attending diverticulitis may produce both a filling defect and obstruction and unless at least a few of the diverticular sacculations are discovered it may be impossible to make a differential diagnosis. The filling defects due to tuberculosis usually involve the proximal colon often with the terminal ileum and there is a surprising lack of palpable mass in consideration of the apparent size and extent of the lesion. Peritoneal Cavity—For a time roentgen study after *artificial pneumoperitoneum* by the introduction of air or gas into the peritoneal cavity was highly recommended as a method of differentiating intra abdominal and retroperitoneal tumors but its popularity has faded until today it is a rarely indicated but nevertheless at times valuable diagnostic aid. This is especially true in countries where hydatid disease is prevalent. Spontaneous *pneumoperitoneum* may be a

Visualization of the urinary tract may be accompanied by retrograde introduction through ureteral catheters of an opaque medium such as sodium iodide or by intravenous administration of some substance prepared for intravenous urography. All films should be exposed during expiration to avoid errors in the diagnosis of ureteral kinks. Before injection of the chosen contrast material a sensitivity test should be made.

Urographic study by one of these methods demonstrates renal anomalies such as horseshoe or ectopic or double kidney or ureter distortions of the renal pelvis by pressure of extrinsic tumors or enlarged adjacent organs, *hydronephrosis* in every degree of change from the simple blunting of the calices to the formation of a large sac, *pyonephrosis* with the principal change in the major calices which at first show irregular moth-eaten edges and later rounded dilatations at their extremities and distention of the renal pelvis, *tuberculosis tumors*, *polycystic kidneys* or unipolar renal cysts.

Congenital ureteral obstructions usually by aberrant blood vessels at or just below the ureteropelvic junction are sometimes characterized by kinking of the ureter often with an indentation corresponding to the blood vessel itself; the resulting dilatation is extensive in the pelvis and comparatively moderate in the portion of the ureter above the blood vessel.

Renal tuberculosis in its early stage can be distinguished only by areas of cortical necrosis; later irregular dilatation of the pelvis, obliteration of one or more of the calices and ureteral stricture are seen. The apices of the calices are most frequently involved showing an indistinct moth-eaten outline, sometimes with detached opaque areas in the renal substance.

Intrinsic tumors such as *neoplasms*, *polycystic*, *large solitary cyst* and *hydatic cyst* not discovered in pyelograms when they alter the normal outline of the renal pelvis or calices. Alveolar carcinoma produces greater pelvic deformity than does *hypernephroma* (papillary adenocarcinoma). Neoplasms may elongate the pelvis or one or more calices; they may encroach on the lumen of the pelvis to the extent of causing flattening or even obliteration of the pelvis

and narrowing of the calices; there may result an abnormal position of the renal pelvis, deformity of the ureter or even its complete occlusion in its upper portion or at the ureteropelvic junction. There is nothing characteristic in the roentgen findings in cases of benign tumors to distinguish them from other forms of neoplasm unless the lesion is accompanied by ulceration and tissue destruction.

The roentgen findings in a case of *polycystic kidney* include shortening or effacement of one or more calices resulting in an oval or irregularly squared pelvic contour. The extension or compression of cysts may cause one or more calices to assume a circular partly circular or broad elongated outline changed in relation to the axis of the pelvis. These findings may be complicated by secondary infection and inflammation. *Simple cysts* sometimes result in striking deformity of the renal pelvis and calices with shortening and compression of the calices and that portion of the pelvis adjacent to the cyst and displacement of the kidney in relation to its normal position and axis. Pressure of an *extrarenal tumor* may closely simulate this deformity. *Hydatid cysts* are usually marked by calcareous deposits in their periphery. Daughter cysts may sometimes be detected.

Urography is a valuable aid in identifying suspicious shadows. One should consider the distance of the shadow from the renal or ureteral outline and the exact relation of the shadow to the visualized urinary tract. Comparison of the plain roentgenogram showing a stone in the region of the kidney or ureter with another roentgenogram after pyeloureterography will improve the accuracy of localization. It is important to determine whether the stone is situated in the true pelvis in a calyx or in the cortex. The use of *roentgenography at the operating table* during the course of the operation is useful in determining the number of stones, their position and whether or not the operative procedure has left behind any of the calculi. A straight lateral roentgenogram of the region will sometimes decide the identity of a suspected shadow, which in the case of a renal calculus will lie well back, superimposed over the vertebral shadow. The identification of suspected ureteral stones is re-

compleished by introduction of an opaque ureteral catheter or by visualization of the ureter with retrograde or intravenous ureterography. The ureterograms in the case of ureteral stone will show complete inclusion of the suspected shadow in the shadow of the ureter dilatation of the ureter above the stone nodular dilatation of the ureter at the site of the stone or with retrograde pyelography dilatation of the ureter below the stone. Stereoscopsy is sometimes of value in determining the relation of the suspected shadow to the ureter when visualized with opaque catheters.

Visualization of the bladder (cystography) by filling it with some opaque medium such as neositol or in the course of intravenous urography is valuable in studying the extent of a neoplasm in the study of *diverticula* as to size and capacity for emptying and in the demonstration of *uretero-vesical insufficiency* vesical obstruction or deformity from pressure from without the bladder. Gaseous media are objectionable for cystography because they may be injurious and the uncertainty of the outline may be confused with gas in the intestinal tract. *Prostatic hypertrophy* is sometimes profitably studied in this manner especially intravesical hypertrophy.

Urethrography is occasionally of value but it cannot replace direct inspection through the urethroscope when it is feasible. Stricture of the urethra with urethral diverticulum and urethral fistulas may be profitably studied in this manner.

OBSTETRICAL AND GYNECOLOGICAL ROENTGENOGRAPHY

The principal indications for *obstetrical roentgenography* are the diagnosis of a doubtful pregnancy the determination of presentation and position the recognition of multiple pregnancy, the question of intra-uterine death of the fetus the diagnosis of extrauterine pregnancy the determination of pelvic and fetal measurements and the study of suspected or evident disproportion and the investigation of the cause of polyhydramnios having in mind especially the possibility of fetal abnormalities.

Theoretically after the ninth week it should be possible to demonstrate on good x-ray films some part of the fetal skeleton

but practically it is not possible to secure routinely satisfactory results before three and one half months i.e. three to six weeks before the appearance of definite clinical signs of fetal life. Near the end of gestation good roentgenograms should reveal even the fetal phalanges and sometimes the carpal and the tarsal. The perfection of the *Ashley-Zondek* reaction has diminished considerably the need of resorting to other means for the early diagnosis of pregnancy. Visualization of the fetus by injecting through the anterior abdominal wall into the amniotic sac a preparation of strontium iodide (*amniography*) is sometimes useful as in the diagnosis of *placenta praevia*. For the diagnosis of pregnancy it is not a justifiable procedure.

Harm to the fetus is not a danger attending ordinary diagnostic roentgen studies such as the determination of pregnancy studies relative to obstetrical problems and gastrointestinal spinal and pelvic examinations but actual exposure to the x-rays should be minimized.

Roentgen measurements of the pelvic diameters can be taken without any special apparatus the ordinary x-ray equipment of a hospital should be satisfactory. Space here does not permit description of the technique of *pelvic and fetal mensuration*.

Fetal monstrosities are sometimes discoverable before delivery especially *anecephaly* *double monstrosities* *hydrocephalus* and other skeletal defects. *Intoleration* shows as a nearly round calcified mass simulating a calcified fibroid. *Ovarian and ectopic pregnancies* may occasionally be recognized especially if uterograms following the introduction of iodized oil into the uterine cavity supplement the ordinary x-ray study.

Death of the fetus in utero may be betrayed by overlapping of the cranial bones which does not occur in labor until after engagement of the fetal head by spinal angulation thoracic collapse and decalcification of the fetal skeletal parts as well as by a disproportion between the calculated age of the fetus and the supposed duration of gestation.

Birth fractures and anomalies of skeletal structures of the newborn child as well as anomalies of the digestive tract diaphragmatic hernia and transposition of the viscera

are of interest. Reference has already been made to studies of the *thymus Atelectasis* is recognized by collapse of the affected lung with displacement of the mediastinum toward the affected side and elevation of the diaphragm on the affected side. Intravenous urography furnishes valuable aid in studying the urinary complications of pregnancy.

By means of a combination of roentgenography with pneumoperitoneum and intrauterine injections of iodized oil valuable aid may be given in *gynecological diagnosis*. Plain roentgenograms are not often of value except in the demonstration of *calcified fibroids and calcareous deposits in cysts and other ovarian tumors*. Calcified fibroids show well but even when not calcified they may be recognized by the displacement of intestinal loops visualized by the opaque meal or enema.

Patency or stenosis of the fallopian tubes and visualization of the pelvic viscera may be established by the peruterine introduction of air or oxygen into the peritoneal cavity. Tubal occlusion may be localized by the intrauterine injection of iodized oil. The combined use of trans-uterine intraperitoneal injections and iodized oil intrauterine injections is occasionally of value in solving special problems. Carcinoma of the uterine fundus should contraindicate attempts at peruterine injections. Double uterus and other uterine deformities are best demonstrated by the use of opaque oils.

Examination of the lungs and other parts of the body for evidence of metastases is especially important after operations on the breast, uterus and kidneys for malignant disease.

ROENTGEN THERAPY

The factors governing the therapeutic administration of x rays are too complex for adequate presentation in a brief space. The use of radium and x rays is recognized universally as the third member of the triad of agencies which have proved most useful in the treatment of malignant diseases, viz. surgery, the cautery and radiation therapy. Long wave (soft ray) therapy for the destruction of superficial malignant growths and other lesions of the skin has been discussed in another chapter and the following discussion will be devoted to deep x ray therapy.

Deep x ray therapy means the use of short wave x rays at 200 000 volts or higher. Its efficiency depends to a considerable extent on the thickness and kind of metal filter used to screen out the less penetrating radiation which cannot reach the depth of the treated tissues and which can only harm the skin. The percentage of radiation which reaches the deep tissue is enhanced by a maximum target skin distance by the use of larger ports of entry (treatment fields) by greater milliamperage (intensity) and by cross fire. Cross fire is obtained by treating the objective lesion through several different areas of skin directing the radiation through each one toward the lesion. The time factor is important as a dose which may be sufficient if administered within a certain time may be altogether inadequate if spread out over too long a period. Increasing the intensity of the radiation (the milliamperage) directly increases the efficiency of the treatment and is of special importance when a long target skin distance is used.

All of the foregoing factors combine to increase the tolerable skin dose and the depth dose in the region of the tumor although at the expense of greatly prolonging the individual treatments and multiplying the number of necessary sittings in each case. Insufficient irradiation is worse than none. Biologic researches have shown the dose in roentgens necessary for definite reddening of the skin (erythema dose), this amount varying according to the wave length and the filter employed and physical means are or should be now available in every hospital and radiological institute for measuring in roentgens the output of all therapeutic x ray apparatus. * As many as four or five tissue doses should be given for most malignant lesions either as a preoperative or as a postoperative measure.

This total dose should be administered in fractions within the shortest time compatible with the patient's reasonable comfort and powers of resistance otherwise an even

* The international roentgen is that quantity of x ray radiation which when the secondary electrons are fully utilized and the wall effect of the chamber is avoided produces in 1 cc of atmospheric air at 0° C and 760 mm of mercury pressure such a degree of conductivity that one electrostatic unit of charge is measured at saturation current. This unit is designated by small r.

greater amount of treatment will be needed. The aim of the fractionated method should be to reach saturation as quickly as possible by large initial frequently repeated treatments and then by smaller doses daily or on alternate days in order to maintain the radiation effect at a maximum for at least thirty days. The direct effect of the x rays is to damage the cells so badly that mitosis is inhibited. Indirect effects include inhibition of the gaseous exchange resulting from the clotting of blood in the vessels shortly after radiation and some immunizing effect brought about by the dying growth. An inoculated tumor tends to avoid growing into an area of tissue which has previously been irradiated. The embryonal type of cell is more radiosensitive than adult forms. The shorter the life cycle of a cell the more sensitive it is to radiation. Lymphocytes are most sensitive and bone and nerve tissues are most resistant. Other important factors influencing the result of radiation therapy include the general condition of the patient and his ability to react to radiation, the nature of the tumor and the proximity of the growth to important normal tissues that may suffer injury. Increased benefits from the fractionated dose method lie in the improvement in the ratio between the destructive effect on the neoplasm and the favorable reaction on the surrounding normal tissue.

The methods of radium therapy have also undergone considerable modification in recent years. Gold and platinum seeds have been substituted for glass seeds in the direct application of radon (the gas of radium) into the tissues. Great care must be exercised in introducing such seeds or needles to secure a uniform distribution in the area under treatment. There is a rapidly growing tendency to use radium as in external application at a distance of 10 cm. or more from the skin, reserving the direct applications for cavities, sinuses and interstitial implantation but the distant application of radium through the working of the inverse square law requires such enormous amounts of radium and such long applications that the method is really not very practicable for the treatment of a large number of patients. Certainly it is not economical. Highly filtered x rays produced at high voltage applied with great intensity from a rather

long target skin distance constitute a serious rival to the external application of radium by radium packs even though they contain enormous quantities of radium.

The results of radiation therapy depend on the application and thoroughness of the planning and administration of treatment in each individual case. Even cases utterly hopeless from the standpoint of surgical treatment sometimes yield good palliative results and five year survivals. Some seemingly inoperable cases become operable. Some conditions formerly treated only surgically are now often referred to the radiation therapist especially cancer of the uterine cervix, many types of skin cancer and cancer of the lip, tongue and pharynx. (See section on Carcinoma of the Lip, Tongue and Pharynx.) In others the question of operability is being more closely studied and in some cases surgical removal of the primary lesion and regional glands has been replaced by irradiation treatment of the primary growth and of the regional nodes with perhaps surgical removal of such regional nodes after treatment.

Biopsy is necessary in a great many lesions. It is believed that biopsy should as a rule be postponed until at least two weeks after beginning roentgen irradiation. Lymphatic drainage should be treated first.

Statistics from the leading tumor clinics of Sweden, Belgium, France, England and America have shown that cancer of the breast gives at least double the number of five year survivals if in all cases the operation is supplemented by adequate radiation therapy preferably preoperative. As a preoperative measure at least 5000 roentgens should be applied through three or four areas over a period of twenty one days as the initial treatment in a case of operable cancer of the breast. If the tumor is operable at least three weeks should intervene after the x ray treatment is finished before operation. An interval of from six to eight weeks is better. Attenuation of the cancerous cells and the sealing of blood vessels and lymph channels limits the dissemination of the disease at the time of operation. Preoperative irradiation in cancer of the breast as a routine measure constitutes the greatest advance in the treatment of this disease. Whether or not postoperative treatment is also to be

given depends on the needs in the individual case. Now that the more rational method of preoperative irradiation is coming into recognition there will be some question as to the technic and necessity for additional irradiation after operation if the preoperative treatment has been given to the point of maximum tolerance. If for any reason adequate presurgical x-ray therapy has not been given the lack should be made up after operation. (See section on Carcinoma of the Breast.)

There are of course cases of cancer in which cure can rarely be expected but in which the palliative results are well worth while as in cancer of the urinary bladder malignant lesions of the kidneys and metastatic malignant lesions of bone.

In primary malignant tumors of bone roentgen therapy accomplishes very little except as a palliative and anodyne. Ewing's endothelioma of bone and multiple myeloma are fairly radiosensitive but are difficult to cure because of the diverse distribution of the lesions or distant metastases. Bronchogenic carcinoma and carcinoma of the esophagus stomach colon liver and pancreas are lesions in which therapeutic irradiation has accomplished little. Early diagnosis and treatment are highly important nevertheless cases which are hopeless for surgical treatment are occasionally benefited by irradiation.

Many lesions of benign character respond to radiation therapy such as tuberculous glands of the neck abdominal tuberculosis and some cases of joint tuberculosis interstitial fibroid tumors when not larger than a three or four months pregnancy and metrorrhagic hemorrhages. Toxic adenomas when not too large usually respond well but the treatments must be continued over a period of three to five months all the doses being suberythemic and with adequate filtration. Furuncles carbuncles cellulitis and erysipelas respond promptly to minimal doses. Recently the employment of x-ray in small doses in the therapy of gas gangrene has appeared very promising. Buerger's disease and Raynaud's disease respond nicely to roentgen therapy over the lumbar symp-

thetic system often averting the need of amputation. The only worthwhile treatment for leukemia is roentgen therapy which is also useful in erythremia Hodgkin's disease and lymphoblastomas of any type.

Roentgen and radium rays penetrate the tissues to a greater or less degree and produce ionization within the tissues their efficiency as therapeutic agents depends upon this ionization. The development of the cyclotron has made possible the preparation of radioactive phosphorus strontium and other elements. Radioactive phosphorus gives off only beta rays which are easily absorbed. This substance localizes in bone and bone marrow and to a considerable degree in the spleen lymph nodes and liver. Radioactive strontium and calcium localize more or less exclusively in bone. The employment of these radioactive elements in the treatment of surgical lesions particularly cancer is as yet in the experimental stage. The results thus far seem to indicate an effect as good as that obtained with roentgen irradiation in prolonging life with some degree of comfort. There seems to be less tendency to irradiation sickness and other reactions. Four elements or compounds—radioactive strontium phosphorus and iodine and chronic radiophosphate are now being used in therapeutic work.

No attempt has been made in the foregoing to cover adequately the field of roentgen therapy but rather to arouse the physician's natural investigative instinct to look at more length into the possibilities of this rapidly developing method of attacking certain diseases.

touch the wound edges with his gloved fingers. He must learn to turn his head away from the field of operation when coughing or sneezing. If he sees a break in technique he must call attention to it.

The student's first duty as a participant in an operation will be retraction. Let him learn it once the art of gentleness, one of the most important principles in aseptic surgery. Every surgeon knows that try as he may the field of operation is never always completely sterile. If tissues are lacerated by rough handling they are all the more sensitive to infection from pathogenic organisms.

Fig. 43.—Packing of drum with linen for sterilization in the autoclave.

Granted that the student has a good understanding of bacteriology, he must realize that everything and everyone that comes in contact with the patient is potentially a source of infection. The patient himself is a potential source. Among the common organisms that cause wound infection are the streptococcus, staphylococcus and colon bacillus; the streptococcus usually causing the most severe infections.

First consider the patient. Organisms are ever present on the skin in the hair follicles and sebaceous gland—therefore the importance of shaving the operative region and cleansing it with soap and water previous to operation. The operator, his assistants and the nurses are sources of infection and they

must protect themselves against infecting the patient. All materials, linen, sutures, solutions and instruments that come in contact with the patient must be made sterile. The operating room itself must be clean. It is essential to learn how all these requirements can be met.

Operating Room—All modern operating rooms are well ventilated and screened. They should be situated on the upper floors of the hospital well away from the general activity. The room itself must not be too large, about 20 by 30 feet. It must contain the minimum amount of furniture and apparatus, thus lessening the amount of contaminated surface. If possible, clean operations should not follow dirty operations—other rooms being used for dirty cases. All visitors must be gowned and masked unless they watch from a screened gallery.

Sterilization of Linen (Fig. 74)—All gowns, caps, masks, sheets, sponges, towels and dressings are packed in drums. These are heated in the autoclave (Fig. 744) which employs live steam under a pressure of 15 pounds for forty-five minutes. This raises the temperature to 121° C. The drums must not be packed too tightly or the heat will not penetrate. Cultures should be taken by the bacteriologist of the various sterile drums at frequent intervals.

Rubber gloves are carefully washed and boiled after an operation. They are then dried, examined for holes and resterilized in the autoclave at a pressure of 15 pounds for fifteen minutes on two consecutive days. More prolonged heating would destroy the rubber.

Water—Sterile water is obtained by boiling previously filtered water in a high pressure water sterilizer at a pressure of 15 pounds at a temperature of 121° C for one hour—one boiler of hot water and one of cold.

Solutions, such as saline, glucose and boric acid are placed in flasks and autoclaved at a pressure of 20 pounds for one hour at a temperature of 126° C.

Rubber tubing, clays and infusion sets, suction tubes, drains and flasks of novocain are sterilized in the autoclave at a pressure of 20 pounds for twenty minutes.

Instruments are thoroughly washed after an operation to remove blood and other or

gum matter. They must be of simple construction to make for easy cleansing. They are placed in trays and boiled for from fifteen to twenty minutes. The temperature is 100°C . A 1 per cent solution of sodium carbonate raises the boiling point about 5° prevents rust and removes grease. Knife blades are dulled by prolonged boiling and must be treated differently. They are boiled for three minutes and then placed in 70 per cent by weight ethyl alcohol for twenty minutes.

Basins are boiled in a special sterilizer for one hour because they are packed closely.

Suture material in glass tubes comes from the manufacturer already rendered sterile by a special technique. These tubes are stored in 5 per cent carbolic acid solution

tion however non absorbable sutures may produce slowly healing foreign body sinuses. The finest possible non absorbable interrupted sutures are recommended for all wounds except those infected or potentially infected.

Setting Up a Sterile Operating Room.—The nurse with all the materials to be used non sterilized proceeds to set up the room. She first puts on her head protector and mask and then proceeds to scrub and gown as described later. The first step is draping the tables after removing the sheets from the sterile drums (Fig. 745). Instruments are then brought in by tray from the adjacent sterilizing room (Fig. 746). Basins are set up and filled with sterile water by the unsterile nurse. This same nurse will on

Fig. 745—Drums and solutions racks preparator to sterilize on the autoclave

and then placed in 70 per cent alcohol for twenty minutes just prior to operation.

Suture material may be of two kinds absorbable and catgut and non absorbable and silk, silkworm gut, horse hair, linen and a fine stainless steel wire. Many surgeons use only catgut for buried sutures. Owing to the continued efforts of Melency, the absolute sterility of catgut is now supervised by the government. The many criticisms of catgut are in regard to its variable absorbability, the deleterious effects of chemicals with production of serum and delayed wound healing and the increased incidence of wound infection dehiscence and postoperative hernia. Many surgeons advocate the use of non absorbable suture materials for buried sutures usually silk. In the presence of infec-

tion the sterile nurse fetching extra sterile drums, solutions or any needed materials. The small instrument tray is prepared. Knife blades and tubes of catgut are removed from the alcohol. Suture tubes are broken and catgut is placed in readiness. Sheets for draping the patient are obtained from the drums and the antiseptic solutions for painting the operative site are made ready.

Masking.—The surgeon also each assistant after donning a clean white coat, trousers and cap puts on a mask which covers the mouth and particularly the nose. This latter is important for any member of an operating room staff, nurse or doctor may be a carrier of virulent streptococci. No member of an operating team, whether doctor or nurse, should enter the operating

room if he has a cold or sore throat. It is well especially in the winter months to have nose and throat cultures taken frequently of those participating in operations.

Fig. 15.—Sterile nurse removes instruments from the sterile drums preparatory to draping the instrument tables.

Scrubbing (Figs 747 to 750).—The care of the surgeon's hands is most important. Nails must be pared, cuticle clipped and the skin kept soft. No surgeon with an infection

Fig. 16.—Hot and cold water sterilizer. The hot and cold water sterilizer is in the background.

of his hands or fingers should operate. Prior to operation the tips of the fingers are placed in half strength (3.5 per cent) tincture of iodine and allowed to dry. The fin-

gers, hand and forearms up to and including the elbows are then scrubbed under hot running water with green soap and a good

Fig. 747.—Dipping the hands in half strength (3.5 per cent) iodine preparatory to scrubbing up. Note the surgeon's coat, trousers, cap and mask covering the nose.

stiff brush for at least five minutes. The hands are then raised and the water is allowed to drip off the elbows. The hands and

Fig. 48.—Scrubbing the hands and arms up to and above the elbows for five minutes.

forearms are then placed in 70 per cent alcohol which is also allowed to drain off at the elbows.

Gown and Gloves—The hands are then dried with a sterile towel (Fig 751). The gown is put on (Fig 752) and the hands

Fig 749—All wing water to drain off the elbows

are carefully powdered with sterile talcum. Figure 753 shows the proper method of putting on gloves care being taken not to

Fig 750—Rising in 70 per cent alcohol

touch the outer part of the glove with the bare hand. While waiting for the start of the operation the surgeon must keep his hands above his waist. If the wait is long they should be covered with a sterile towel.

Antiseptics—So far only sterilization by heat has been discussed. It is obviously impossible to utilize this method of obtaining asepsis in connection with the skin of the patient or the skin of the surgeons and nurses. Half strength (3.5 per cent) tincture of io

Fig 751—Drying hands with a sterile towel. The table holds gowns, gloves and sterile powder can

dine has been found to be satisfactory in preparing the operative site. It is put on when the skin is dry, otherwise it will not penetrate. It is most important that it be allowed to dry and then removed with 70 per cent alcohol (Fig 754).

Fig 752—Nurse tying up the surgeon's gown

Alcohol 70 per cent is used to finish the sterilization of tubes of catgut and knife blades.

Bichloride of mercury in 1:5000 solution is used for washing the gloved hands during

the operation. This should be removed by rinsing in sterile water.

Fig. 753—The proper way for the surgeon to put on his gloves.

Carbolic acid (5 per cent) is used for cauterizing the appendix stump or the cut ends

in surgery, but these are perhaps the most valuable.

Draping the Patient.—After the site of operation has been prepared with iodine and alcohol, if for a laparotomy, a small towel is placed just above the pubes and fastened to the skin with two towel clips. Two large sheets are then draped, one over the foot of the table reaching up to the lower margin of the operative field and the other over the head of the table reaching down to the upper margin of the field and draped over the ether screen. Four towels are then affixed at right angles to one another, leaving room for the skin incision (Fig. 755). Finally, a large sheet with a central opening is placed over the entire table. The small instrument tray is brought over the foot of the table and adjusted to the proper height. The surgeon, his assistants and the nurses then take their proper positions and the incision is made (Fig. 756).

The sterile field must be made as small as possible in order to avoid 'unsterilizing'. The assistants must keep their hands in the field; they must not reach for instruments behind the operator (Fig. 757).

Any instrument which partially slips off the table is unsterile and must not be touched. Any break in the sterile technic must be immediately reported, though it means the setting up of an entire new sterile operating room rather than run the

of other hollow intra-abdominal organs. Carbolic acid (5 per cent) is used to store tubes of excreta. Many other antiseptics are used

risk of having a severe infection develop in the patient and possibly cause his death.

In spite of all the many safeguards that

Fig. 757.—An improper way of handing instruments—behind the operator.

have been discussed there are still weak links in the chain of aseptic surgical technique. Melenev³ in 1935 in a study of the bacterial flora in his operating room estimated that from 35 000 to 60 000 bacteria fall on the operative field during the course of an hour. In other words every wound under usual operating room conditions is contaminated. Fortunately few wounds become infected probably because of the natural resistance of tissues and the fact that different individuals vary in their susceptibility to infection. Nevertheless the average incidence of infected wounds today is from 4 to 6 per cent, sometimes rising as high as 20 per cent.

How can the number of air borne bacteria in an operating room be reduced? A number of procedures have been proposed to reduce infection of clean surgical wounds to an irreducible minimum. One must mention particularly the work of Hart⁴ who proposed the destruction of air borne bacteria in an operating room by bactericidal radiant energy through continuous special ultraviolet radiation of the air and the field of operation. His work is most encouraging. The use of proper masks for the operating room personnel is obvious. However the perfect mask which absolutely prevents the outflow of bacteria from the nose and throat has not been found. Most masks used today by sur-

geons deflect bacteria from the operative field rather than filter them from the expired air. Arnold⁵ believes that cellulose wadding is the best material for filtering the expired air. It is far better than the cotton gauze commonly used. De Takats⁶ suggests the use of a flannel mask which he claims successfully filters the expired air. Stage Davis⁷ suggests the use of two masks covering both mouth and nose each consisting of three to four thicknesses of woven muslin 60 to 65 strands to the square inch.

Jackson⁸ believes that mechanical cleansing with soap and water just before the closure of a clean surgical wound is not harmful to good wound healing and will prevent the small percentage of infections that still remain as a plague in every surgical clinic.

XXXIX. MINOR SURGICAL PROCEDURES

Hypodermoclysis—Hypodermoclysis is the term applied to the subcutaneous infusion of large amounts of fluids. Favorite sites for hypodermoclysis are the loose subcutaneous areolar tissues of the thighs and low in the axillae or flanks and the submammary connective tissue. For infants the subcutaneous tissue of the back or buttocks may be preferable. Following prolonged inhalation anesthesia it is not advisable to give submammary infusions because of the danger of further embarrassing the respiration and thus predisposing to pulmonary complications. The apparatus most commonly used consists of two long needles (3 or 3½ in.) connected by means of a glass Y and rubber tubing with a sterile container which is suspended approximately 2 feet above the level of the patient. The rate of flow is controlled by a clamp on the tubing just below the bottle and by using needles of small caliber (18 or 20 gauge), overdistention of the tissues should be avoided so as not to cause the patient any unnecessary discomfort. Woodruff¹ advocates the use of several small needles in order to accelerate the rate of absorption and to prevent undue distention of the tissues, these are connected with the central apparatus by means of rubber tubes and a Carrel-Dakin glass connecting piece. Solutions must be carefully prepared; the ones most commonly employed are normal saline and 5 per cent dextrose Ringer's solution. The rate of flow should not be greater than 500 cc. per hour when multiple needles are used the amount can be increased proportionately.

Intravenous Infusion (Venoclysis)—Intravenous infusion implies the introduction of large quantities of fluid into a vein. A No. 19 or 20 gauge needle is inserted into any suitable superficial vein. Difficult veins may necessitate the use of a cannula after cutting down on the vessel. In this event the vein should be isolated from its bed and two catgut ligatures thrown around it, the distal one tied and the proximal one left loose until the infusion has been completed. After the

distal ligature has been tied the vein is partially incised transversely with sharp pointed scissors and the cannula slipped into its lumen through the incision. With moderate skill and a sharp needle it seldom should be necessary to cut down on a vein. In intravenous work more failures are due to a dull needle than to any other single factor. Once the needle or cannula is properly placed in the lumen of the vein it is connected with a piece of rubber tubing (all air having been expelled from the tubing by allowing the solution to run through it) which leads to a buret or volumeter flask supported near the bed (Fig. 758). The rate of flow is regulated by the height of the flask above the vein and by a clamp on the rubber tubing. The drip chamber shown in figure 758 provides an excellent indicator for regulating the rate of flow. Woodruff recommends that the rate of flow be determined by the body weight: i. e. 4 cc. per minute for a patient weighing from 100 to 150 pounds and 5 cc. per minute for a patient weighing from 150 to 200 pounds. This is of especial importance when dextrose solution is being used as the patient can absorb only 0.8 Gm. of glucose per kilogram of body weight per hour. Glucose given in quantities exceeding this amount acts as a diuretic and a dihydrant. Solutions which may be used for venoclysis are normal sodium chloride 5 to 20 per cent dextrose solution (5 per cent dextrose is most nearly isotonic with blood), gum racia, Hartmann's solution, plasma, blood serum and compatible whole blood. All solutions for intravenous use should be prepared with extreme care so that no reactions will be caused by them. Only fresh solutions should be used and these must be bacteriologically and chemically pure. Certain of the commercial laboratories have prepared solutions for intravenous and subcutaneous use which are put up in sealed glass containers thus making this form of therapy available to the general practitioner.

Blood Transfusion—The technique of blood transfusion has been so greatly simplified

fied in recent years that its use is now available to physicians everywhere. Formerly it was a hospital procedure but now blood can be readily given in the home on the battle field or on ships at sea.

Selection of the donor is of prime importance. Syphilis in the donor must be carefully excluded both by history and by the Wassermann test. A recent attack of typhoid fever, diphtheria, malaria, influenza, tuberculosis or rheumatism should disqualify a prospective donor. The blood of the donor

Group II (A—Landsteiner)—Serum agglutinates corpuscles of groups I and III. Corpuscles are agglutinated by sera of groups III and IV (Approximately 40 per cent of all persons belong in group II).

Group III (B—Landsteiner)—Serum agglutinates corpuscles of groups I and II. Corpuscles are agglutinated by sera of groups II and IV (Approximately 7 per cent of all persons belong in group III).

Group IV (O—Landsteiner)—Serum agglutinates corpuscles of all other groups.

Fig. 58.—Illustration of fluid (A special type of drip chamber containing a filter is used for blood).

should be typed and if it is found to be of the same group as that of the recipient the bloods of the two should be cross typed. Failure of agglutination with the cross typing indicates compatibility of the two bloods.

Blood Grouping—Moss² found that all bloods could be classified into four groups according to their agglutination reactions.

Group I (AB—Landsteiner)—Serum does not agglutinate the corpuscles of any group. Corpuscles are agglutinated by sera of groups II, III and IV (Approximately 10 per cent of all persons belong to group I).

Corpuscles are agglutinated by none of the sera (Approximately 43 per cent of all persons belong in group IV).

For Lee's technique of blood grouping there should be kept on hand fresh sera of persons belonging to groups II and III.* To carry out the tests a suspension of the donor's red cells is prepared by placing two or three drops of his blood into 1 cc of citrated salt solution. A platinum loopful of standard group II serum is deposited on a slide and

* Stock sera obtained from one of the biological laboratories are recommended for general usage.

in it is emulsified a loopful of the donor's red cell suspension. The agglutination can be observed with a low power magnifying glass. Agglutination when it occurs is complete in from five to fifteen minutes. The test is repeated with group III serum (this may be done simultaneously for expediency). If both sera agglutinate the donor's cells he belongs to group I. If neither agglutinates them he belongs to group IV. If agglutination occurs with group II serum and not with group III the donor belongs to group III. Agglutination by group III serum but not with group II puts him in group II.

Cross typing is done by mixing a loopful of the donor's cells with a drop of the recipient's serum. If agglutination occurs the donor should be rejected even though he belongs to the same group as the recipient. Guthrie and Huck have demonstrated the existence of subgroups which the usually employed methods of blood grouping fail to detect.

In an emergency it may be necessary to dispense with the time consuming procedure of grouping the bloods. In such instances compatibility can be directly and quickly determined by cross typing. It is advisable if expediency permits to select a known group IV donor. However the cross matching never should be omitted.

Methods of blood transfusion in most common use today are the indirect or citrate method of Lewisohn⁴ and the direct methods of Landmann, Kumpston, Brown, Unger and Seannell.

Citrate Method—This method is the one most widely used today. The procedure as described originally by Lewisohn has been variously modified but its essential features are unchanged; these are (1) collection of the blood from the donor, (2) addition of sodium citrate (10 cc. of a 2.5 per cent solution for each 100 cc. of blood) and (3) introduction of the citrated blood into the recipient's vein (Fig. 758). The use of a sealed flask for collecting the blood represents the most significant improvement over the original technique. For the procedure as carried out by our transfusion team the following materials are required: (1) two needles of sufficiently large gauge to insure free passage of blood through the lumen (a No. 15 or 16 gauge needle is recommended for the donor's

vein and a No. 19 or 20 gauge for the recipient's); they must be sharp and should possess a short bevel. (2) a vacoliter flask fitted with a rubber stopper and containing 70 cc. of 2.5 per cent solution of sodium citrate in normal saline solution. (3) a second piece of rubber tubing (15 to 18 inches long) fitted with an adaptor at one end and the special valve with attached needle at the other (Fig. 759 B), (4) a hypodermic syringe containing a 1 per cent solution of novocain and (5) an ordinary vacoliter type of intravenous set. The apparatus is assembled as shown in figure 759 and the blood flow from the donor's vein is regulated by means of the valve. The negative pressure in the sealed flask insures a steady flow.

A blood pressure cuff is placed on the donor's arm to serve as a tourniquet and the arm is prepared as for any intravenous infusion. Prior to insertion of the needle a drop of 1 per cent novocain shall be injected intradermally over the vein selected. Dodd says: "This anesthetic is not a courtesy to donors; it is a right." The needle is then inserted into a large vein, preferably directed peripherally. The rate of the flow of blood from the donor is regulated by the valve mechanism. As the blood flows into the flask it is agitated gently to insure mixing with the citrate. Violent agitation should be condemned because of the danger of destroying the platelets and cellular elements. Use of this technique makes certain that the blood is at no time exposed to the air. When the desired amount has been obtained the needle in the donor's vein is withdrawn and the valve with its attached needle is removed from the rubber stopper in the vacoliter flask. The flask is then transported to the patient's room; the rubber disk which seals the air vent and the hole for the attachment of the tubing of the recipient set is torn away from the stopper and the flask is substituted for the flask in the intravenous set which is in operation at the recipient's bedside (Fig. 758). A metal filter set is attached below the flask containing the blood. The infusion should be given slowly (forty minutes to an hour being allowed for 500 cc. of blood) and measures adopted to prevent the blood from becoming chilled before it enters the recipient's circulation; this is accomplished by immersing the rubber tubing

of the intravenous set in a basin of water maintained at slightly above body temperature

The donor's arm should be carefully bandaged following the withdrawal of the needle in order to prevent the development of a hematoma or secondary infection. He should be instructed to remove the bandage in from twelve to twenty four hours.

The advantages of the citrate method are several (1) It is simple and applicable for

effect. However it has been shown that temporarily the coagulation time of blood actually is decreased following the injection of citrated blood. A more plausible objection is that of the destructive action of the drug on the complement thus reducing its phagocytic and opsonic powers. The latter contraindicates its use in cases of sepsis or in the presence of general infections. Administration of heparin to the donor just prior to transfusion has been proposed. In this way

Fig. 739.—Commercial vacoliter flasks such as the one shown in this illustration have greatly simplified the withdrawal of blood from a donor. The rubber stopper is covered with an airtight rubber disk to preserve the vacuum. The special needle which is attached to the valve mechanism is passed through this rubber disk after being connected with the rubber tubing. After the needle is inserted into the donor's arm the valve is carefully opened and regulated so as to produce a brisk, steady flow of blood. When the desired amount of blood has been taken the valve needle is withdrawn, the airtight rubber disk is peeled off and the tube to the recipient (which contains the metal filter) is connected with the flask by the insertion of a glass tube in the rubber stopper. The flask is then inverted and suspended from a stand at a height to insure flow by gravity.

use by the general practitioner and (2) it permits transportation of blood before use (3) avoids all possibility of infecting the donor (4) minimizes the danger of clotting and (5) requires no assistants. The disadvantage most commonly mentioned in connection with this method is that the blood is altered by the addition of an anticoagulant. Sodium citrate has a tendency to destroy blood platelets and this would seem to contraindicate its use for hemostatic

the clotting time of the donor's blood can be prolonged sufficiently to obviate the necessity for using sodium citrate. However heparinized blood should not be given when hemostasis is of concern.

Blood Transfusions in Infants—For infants transfusion requires the utmost precision and should not be undertaken by one unskilled in intravenous technique. The great saphenous vein just anterior to the medial malleolus and the small saphenous vein just

posterior to the external malleolus are the veins of choice because of their relatively large caliber and the better chance of immobilization of the part. The latter can be accomplished by placing a small wooden splint along the outer aspect of the leg opposite the operative field and fixing it in place with adhesive strips. The foot should be strapped to the splint in the position of plantar flexion if the great saphenous is to be used. A preliminary intradermal injection of novocain is advisable in order to minimize subsequent struggling on the part of the infant. With a lancet pointed scalpel a small incision (1 cm.) is made in the skin overlying the vein and the latter elevated into view with the aid of a small fine pointed tissue forceps this being used as a skid rather than to grasp the vein. Once exposed the vessel is opened with a delicate fine pointed scissors and a No. 19 gauge needle with a 45 degree bevel inserted. The needle can be held in place with an 00 catgut ligature or better by clamping it just above the opening in the vein with a specially constructed mosquito forceps through the blades of which near the tip a hole has been drilled which is just large enough to grasp a 19 gauge needle. Citrated blood is then injected. Gentle pressure will control leakage of blood from the vein following with drawal of the needle thus preserving the vein for future use.

Refrigerated Blood—Citrated blood may be preserved in a refrigerator at 4° C for as long as two weeks without serious deterioration. Studies by Bull and Drew² revealed as the outstanding changes in refrigerated blood a loss of white cells and platelets an increase in plasma potassium and a decrease in prothrombin. However for most clinical purposes it should give the same results as fresh blood. Transitory jaundice has been observed in recipients given preserved blood which has been stored for nine or more days. Because of this limited period of usefulness it is probable that refrigerated whole blood will give way to the use of plasma which is becoming recognized as an excellent substitute for whole blood and can be stored for a much longer time.

Direct Method—The Scannell apparatus consists of a three-way stopcock with rubber tubing and adaptors for each of the three

fittings two cannula type needles and several 25 cc special Luer syringes.

In former years the direct method of blood transfusion was widely used but with the increase in popularity of the citrate method it has become almost obsolete.

Advocates of the direct method of transfusing blood claim for it the advantages of (1) the use of unmodified blood (2) less chance of contamination (3) no disturbance to the platelets and (4) less chilling of the blood.

The disadvantages of this method are that (1) special apparatus is required (2) the donor and recipient must be in the same room with consequent psychic trauma to the patient and (3) if blood clots in the apparatus this may be difficult of correction.

Reactions—It is doubtful if the method employed *per se* has any influence on the incidence of reactions following transfusions. Studies conducted by Lawisohn³ and Lundberg⁴ lend conviction to the conclusion that post transfusion chills with an elevation of the temperature are due to (1) improper cleansing and sterilization of the material used (2) imperfect technique of transfusion or (3) incompatibility of the donor's blood with that of the recipient.

Plasma Transfusion—In recent years the therapeutic value of human plasma and serum as a substitute for whole blood has been definitely established and its numerous advantages are being demonstrated daily in the present world war. The problem of surgical shock long has occupied the attention of medical investigators and numerous theories have been advanced to explain this physiologic phenomenon (See section on Shock). The principal advantages of plasma or serum over whole blood are that it can be safely stored for long periods and that it does not require typing before infusion. Plasma may be prepared from fresh citrated or heparinized blood or from stored or preserved whole blood. The cells may be separated either by centrifugation or by sedimentation. The former is the practice in large hospitals or where large amounts of plasma are needed and is accomplished by use of large centrifuge flasks. It has the advantages of speed and elimination of blood clot. Regardless of the method used in

separating the cells, the plasma is aspirated aseptically and, after testing for pyrogens and sterility, is stored at room temperature,

Plasma may also be dehydrated and stored in the dried state, but this is a complex, costly and difficult procedure. Dried plasma,

Fig 760—Technic of intubation 1 the component parts of a tube for the small intestines a, The aspirating tip size 16 F, b, double-lumen tube with perforations from the small lumen for inflation of the balloon and into the large lumen for aspiration of intestinal contents c, metal connections d round rubber tubing connecting the apparatus to aspirating bottles or to a syringe for the injection of air (the rubber balloon is cut to the correct size before being tied on the tube) It is of great importance in assembling a tube to safeguard against blockage by seeing that the diameter of the lumen of every part from tip to bottle increases progressively 2, the tube assembled for aspiration both ahead of and behind the balloon In 2a is shown the importance of a loose balloon that can sag forward temporarily covering the tip as it advances 3 the tip is mounted on the small lumen so that the balloon precedes the tube an assembly that is particularly useful in the presence of multiple adhesions 4 the balloon on a separate tube draws a single-lumen aspirating tube after it, a device used chiefly in cases of multiple partial obstructions 5 and 5a the fluoroscopic appearance of tubes at the point in the duodenum at which the balloon may safely be inflated without fear of its being regurgitated back into the stomach 6 and 6a the way in which a tube is believed to empty the intestine segment by segment, deflating it allowing the blood supply to return and then being advanced to the next point of angulation by the returning peristalsis *

at 4° C, or is frozen Freezing is the best procedure, as no bacterial growth and no precipitation of fibrin occur at this temperature Frozen plasma will keep indefinitely.

however, has the important advantages of reduced bulk and sterility under any conditions of temperature. It can be regener-

* Abbott Arch Int Med 63

ated in ten to fifteen minutes by the addition of sterile distilled water. For these reasons this type of plasma is used by the Army in the field.

For routine use the most satisfactory method of keeping plasma is in the frozen state. Any mechanical refrigerator will accommodate a few bottles (250 cc of plasma in a 350 cc bottle). For prolonged storage, however, in icecream cabinet or other below zero unit should be employed. Frozen plasma is melted at 37° C and can be administered within fifteen to twenty minutes after being ordered.

Proctoclysis (Murphy Drip)—Rectal infusion represents the simplest method of supplying fluids to the unconscious patient. When well tolerated it can be substituted for parenteral clisters throughout convalescence. It requires no elaborate apparatus or sterile solutions and can be given by any intelligent nurse. Luckhart has shown that of the glucose solutions the 1 per cent concentration is absorbed most rapidly and is least irritating to the colon. *Retention enemias* may be substituted for the Murphy drip to supply fluids postoperatively. For this purpose from 4 to 6 ounces of a 1 per cent solution of glucose is given through a catheter at four hour intervals. Stimulants (whisky, brandy, coffee, etc.) and sedatives (bromides, chloral, etc.) may be administered as retention enemias.

Phlebotomy—Phlebotomy (venesection) is the term applied to the opening of a vein for blood letting. As a therapeutic measure blood letting no longer enjoys the popularity it once held. However, it is a useful procedure in certain forms of hypertension, menorrhoea, polycythemia vera and congestive heart failure.

Gastric Lavage—Washing the stomach is accomplished by passing a stomach tube or nasal catheter (Levin tube) into the stomach. The latter is better tolerated by most patients and since it is less likely to be accompanied by retching is recommended for postoperative aspiration. The catheter should be lubricated with mineral oil and gently introduced through the nares when the pharynx is reached the patient is given a glass of water and a straw and instructed to swallow. The tube can be inserted without difficulty while the patient swallows the

water. After the tube has reached the stomach a syringe is attached and the gastric contents are aspirated.

Wangensteen Suction Apparatus—The Wangenstein suction apparatus consists essentially of a water siphonage outfit, a calibrated bottle for measuring aspirated gas and a Levin catheter. If the Wangenstein suction apparatus is used longer than two or three days the danger of esophageal erosion should be kept in mind. (See section on Intestinal Obstruction.)

Intestinal Intubation (Miller Abbott Tube)—Intubation of the small intestine by means of the Miller Abbott tube has proved to be a valuable diagnostic and therapeutic aid in a variety of intestinal conditions. Decompression of the bowel by this means is particularly effective in paralytic ileus and non-stringulation types of obstruction. The apparatus consists of a three-bottle Wangenstein system and a double-lumen tube with an inflatable rubber balloon at the tip. One of the inner tubes is an aspirating tube, the other is a tube for inflating the balloon. The housing tube should be 10 to 12 feet in length with a circumference of 10 mm (Fig 760). The chief obstacle to successful use of the Miller Abbott tube lies in the difficulty so frequently encountered in passing the tip beyond the duodenum. This difficulty is naturally increased in the presence of intestinal obstruction. Abbott⁷ says: "In most instances the best results are obtained by using more patience than most men can readily muster in the presence of a critical situation. His description of the technique for passing the tube is as follows:

1. Insert an applicator wrapped with cotton to the diameter of the tube for 3 in. of its length and saturated with 2 per cent povidone in the s.d. of the patient's nose which admits it most freely. The tip should not advance past the posterior nasopharynx.
2. Test the patency of both tube lumina with a syringe and test the balloons under water for leaks.
3. Lubricate the tube and empty balloon with oil.
4. Remove the applicator and pass the tube in through the nose until the tip enters the stomach. As a rule vomiting ensues but the patient should suffer less if the stomach is not empty.
5. Place the patient prone with the head to the left, or as nearly in this position as possible.
6. Inject 500 cc of air not into the balloon but into the patient's stomach. Advance the tube to the 75 cm mark in a small patient or to 80 cm in a large one. Connect the suction apparatus

to the tube for the immediate withdrawal of the injected air and the intestinal contents that an obstructed bowel intermittently regurgitates into the stomach. The purpose of this procedure is to listen to the stomach enough to allow the tip of the tube to pass from the left to the right hand portion for in the presence of intestinal obstruction the antrum and body of the stomach are in tight contraction and a tube passed without this precaution will coil in the fundus. The tube should be taped to the patient's nose and the patient allowed to remain in this position for an indefinite period until the tip enters the transverse portion of the duodenum. In general the period for which it is safe to wait depends on the state of the patient. In the absence of strangulation the patient will improve hour by hour from the withdrawal of intestinal gas and fluid which finds its way back to the stomach. Intravenous infusions or blood transfusions may be given at this time and fluid by mouth if as much is aspirated as is swallowed. A 0.45 per cent salt solution may be drunk but if this is distasteful 0.6 Gm sodium chloride in capsules should be given for every 100 cc of drainage. The tube cannot be passed further until the balloon has entered the third part of the duodenum or inflating it will cause its regurgitation back into the stomach. Its position may most easily be checked at frequent intervals by applying a dry clean glass 50 cc syringe with a smoothly ground barrel to the balloon lumen and injecting 10 cc of air. With practice it soon becomes possible to recognize the characteristic feel of duodenal contractions as transmitted to the syringe plunger. A more certain method is to take a bedside film aimed at the upper abdomen. Fluoroscopy is the most certain but the most trying procedure to the patient. When in place the balloon should be filled with 25 cc to 30 cc of air but no more and the air passage clamped. It is well to test the balloon occasionally thereafter in case a leak has developed. The attendant nurse should from this time on pass 6 in of the tube into the patient's nose each hour retaining it with tape. If the balloon is pulling the tube out of the stomach as fast as it is being introduced no nausea will accompany this procedure. Should the patient silently begin to choke on the tube no more should be passed than goes in without gagging as it is probable that the tip has reached the obstruction and is no longer advancing. The tape should be removed from the patient's nose at this time if the obstruction is mechanical. In a case of paralytic ileus when distention has been relieved the balloon may be emptied. It is then safe to allow the tube to remain taped to the patient's nose indefinitely. From the time the tube reaches a position 3 ft beyond the pylorus food as well as drink should be given in five small feedings daily as tolerated. Since the residue must be aspirated through the tube it is important that a low residue diet be selected. I prefer to begin with the half strength physiologic saline referred to above and to all in the following order: dilute strained fruit juices, clear unseasoned soup, tea, coffee, rice, melba toast, soft cheese, meat or fruit, yellies, farinae, lean mutton, beef and lamb, boiled or baked fish, mashed potato, milk, butter and puréed vegetables. Sugar and salt are used freely and skim milk in tea, coffee and on cereals at any time. If the tube is

to remain in place for more than a few days routine examination of the nose and throat is advisable. If ephedrine or a comparable substance is used routinely in the nose and if the patient is urged to eat little difficulty need be anticipated from mucosal irritation. The tube is removed by emptying the balloon and withdrawing 1 ft every fifteen minutes. If the balloon has been expelled by rectum cut off the tube at the nose and withdraw it at the same rate from below. In an emergency it may be necessary to use a wire stylet and pass the tube with the aid of the fluoroscope.

Spinal Puncture—Spinal puncture (rachicentesis) is the introduction of a needle into the subarachnoid space. It is indicated (1) to relieve spinal fluid pressure, (2) for spinal fluid analysis and (3) for spinal anesthesia.

Technic—Unless the patient is too ill to be moved he should be placed on a table before spinal puncture is attempted. He is then instructed to lie on his side, clasp the knees with his hands and draw them tightly against the abdomen, flexing the head and shoulders at the same time. This will arch the back and widen the intervertebral spaces. A small pillow or folded sheet is placed under the head for comfort. The shoulders and iliac crests should be perpendicular to the table. Proper attention to these details will facilitate the introduction of the needle into the subdural canal.

Having satisfied himself that the patient is in the correct position, the operator should carefully asepticize the skin for a considerable area around the site chosen for the puncture. This is best done by thoroughly scrubbing it with ether and applying two coats of a 2 per cent solution of iodine. Sterile towels draped over the unprepared skin will provide additional protection against contamination. The fourth lumbar interspace is the site usually chosen for spinal puncture. When this space has been located by approximating the center of a line connecting the two iliac crests it is carefully palpated with the thumb of the left hand and the overlying skin anesthetized with a 2 per cent solution of novocain.

The spinal puncture needle should be of strong yet flexible material. A short bevel with a sharp cutting edge will minimize the danger of injury to the nerve filaments of the cauda. A 20 gauge needle is best for diagnostic puncture and drainage, while a smaller needle (22 gauge) is recommended

for use in spinal anesthesia. In performing the puncture the shaft of the needle is steadied with the first three fingers of each hand the thumbs controlling the base and inserted in the midline through the middle of the interspace with the shaft perpendicular to the skin surface (Fig 761). Resistance will be felt when the interspinous ligament is reached and again when the needle point comes in contact with the dura. There is a sudden release when the dura is punctured. The stylet is then withdrawn and the spinal fluid collected in sterile test tubes. A free flow indicates a satisfactory puncture; if the flow should stop it usually can be reestablished by rotating the needle 90 degrees care being taken not to change its position otherwise unless the stylet is rein-

serted and roentgenologic examination. If the scapula interferes it may be moved forward and laterally by having the patient place the hand that corresponds to the affected side on the tip of the opposite shoulder. Appropriate drapes of sterile towels should then be applied.

A small wheal is raised in the middle of the desired interspace by the injection of a small quantity of a 1 per cent solution of novocain. A larger needle should then be used for thorough infiltration of all intercostal tissues as far as and including the pleura. Perforation of the parietal pleura may cause some distress. This can be decreased by slowly injecting the anesthetic substance as the needle proceeds. An additional advantage in slowly introducing the needle is that it in-

Fig 761—Lateral position for spinal puncture. Site of puncture is at x.

serted. The spinal fluid pressure may be measured by connecting the needle to a manometer.

Thoracentesis—Surgical puncture or tapping of the thoracic wall usually is referred to as thoracentesis, although the terms paracentesis thoracis and pleurocentesis frequently are used. Under ordinary circumstances the procedure is simple and may be carried out in the patient's room. If the condition of the patient will permit, however, he should be taken to the operating room and placed in a sitting position. A wide area around the point through which the needle is to be inserted should be well scrubbed with ether and two coats of 2 per cent iodine (or some other recognized antiseptic) should be applied. The point of aspiration can be determined only by per-

ussion obtained as to the situation of the tip of the needle. If injection suddenly becomes easier after slight increased resistance the tip is probably in the pleural space. Withdrawal of the plunger should cause pleural fluid to flow into the syringe. If no fluid is obtained the needle probably was not inserted far enough. If bloody frothy material is obtained the tip of the needle probably is in pulmonary tissue and should be withdrawn.

The most important point to remember is that the intercostal vessels course along the lower borders of the ribs and that serious hemorrhage may result from injury to these vessels. Pneumothorax may be avoided by meticulous care in the application of

* Clinebpler: Minor Surgery. W. B. Saunders Co. Publishers.

syringe or rubber tubing to the needle the tip of which is in the pleural space. A large quantity of air can be drawn into the pleural space during inspiration even through a needle of small gauge. A sufficient quantity of pleural fluid for bacteriologic examination can be obtained with a small syringe. For removal of larger quantities a large bottle from which the air has been exhausted with a vacuum pump will be found to be of great convenience and the possibility of producing pneumothorax is decreased because of the less frequent change of apparatus. A small sterile sponge should be placed over the puncture wound after the needle has been withdrawn.

Paracentesis Abdominis.—Paracentesis abdominis is indicated in cases in which an excessive quantity of ascitic fluid has accumulated in the peritoneal cavity. With the patient seated in a chair the midline of the abdomen 2 to 4 inches below the umbilicus is the puncture site most commonly chosen as it insures dependent drainage and is an area of abdominal wall which is relatively avascular. The skin is painted with iodine and the puncture site anesthetized by infiltration with 1 per cent novocain solution down to the peritoneum. A small incision is then made in the skin with a lancet-pointed scalpel and the trocar carefully pushed through the abdominal wall increased resistance followed by a sense of release indicates that the peritoneal cavity has been entered. Failure to obtain a free flow of fluid usually means that the intestine or omentum is obstructing the open end of the cannula. This can be remedied by reinserting the mandarin and gently rotating the trocar. Too rapid withdrawal of fluid should be avoided because of the danger of syncope. Christopher⁸ warns against the danger of perforating the intestine in cases of tuberculous peritonitis and suggests that this condition be ruled out before aspiration is attempted.

Aspiration of a Hydrocele.—Aspiration is a palliative procedure for an excessive accumulation of fluid in the tunica vaginalis. An intradermal wheal of novocain at the puncture site will be appreciated by the patient. The scrotum is grasped with the left hand so that the testis which lies posterior to the hydrocele is out of the way. A small

trocar or large hollow needle is then inserted at the anterior dependent portion of the scrotum and directed upward and forward. In cases of moderate distention in which the testis lies in the dependent portion of a large scrotal sac Croft⁹ advocates introducing the needle anteriorly at the upper limits of the hydrocele directing its point downward and anterior to the testis.

Aspiration of a Joint.—Aspiration of a joint may be required to relieve pressure to obtain fluid for bacteriologic study or to irrigate a joint cavity in cases of infection. An aseptic technique should be carefully observed in all instances in which the joint cavity is to be entered. In aspirating the knee joint the needle is inserted 1 inch to the outside of the patella¹⁰ and carried toward the middle of the joint. The point at which the needle is inserted for entering the hip joint is midway between the great trochanter and the intersection of the femoral artery with Poupert's ligament. The shoulder joint is approached from the posterior aspect the needle being inserted just distal to the base of the acromion process between the posterior border of the deltoid and the tendon of the infraspinatus. The needle is directed toward the index finger of the surgeon's free hand which is placed on the coracoid process in front. (A small preliminary skin incision is advised for all cases in which an uninfected joint is to be aspirated.)

Intubation.—Intubation is the introduction of a hard rubber tube into the larynx for the relief of threatened asphyxiation. It is usually done in cases of laryngeal diphtheria in which the larynx has become so edematous as to interfere with respiration and for asphyxia neonatorum. A sheet is wrapped around the patient's body including the arms and the head is steadied by an assistant. A mouth gag should be inserted to prevent closure of the jaws. The index finger of the operator's left hand is introduced into the pharynx as far as the epiglottis which is lifted up while the tube with its carrier is inserted into the back part of the mouth with the right hand. The tube is carefully directed into the larynx over the operator's left index finger as a guide. The obturator is then withdrawn and the silk thread which is attached to the intubation

tube is anchored by adhesive plaster to the outside of the cheek.

Peritoneoscopy—The rapid growth in the popularity of endoscopic procedures has come to include visualization of the peritoneal cavity and its contents. Although its usefulness is somewhat restricted to certain chronic conditions (suspected carcinomatous metastases, cystic tumors, etc.) valuable diagnostic information may be obtained and laparotomy avoided. The endoscope is introduced into the peritoneal cavity through a stab wound in the abdominal wall following the injection of air through a pneumoperitoneum needle. Further distention is carried out by means of an air bulb which is connected with the scope. The peritoneal cavity and its contents then become visible with proper manipulation of the scope.

Resuscitation—Cessation of respiratory and circulatory activity following prolonged submergence, carbon monoxide poisoning, electric shock, traumatic shock, operating room accidents and so forth call for prompt and intelligent action.

Artificial respiration is the principal aid to resuscitation in cases of drowning, gas poisoning and electric shock. The prone pressure method¹¹ is advocated for such emergencies. For asphyxia in the operating room, Silvester's method of producing expiration by compressing the sides of the thorax with the patient's arms grasped with the hands of the operator and obtaining inspiration by fully extending the arms to the sides of the patient's head is recommended. In all such instances a finger should

be inserted into the anus for the purpose of dilating the anal sphincter as this maneuver is often followed by a dramatic respiratory response on the part of the patient. Bibcock¹ emphasizes the value of mouth to mouth insufflation in such emergencies. In cases of asphyxia during the induction stage of anesthesia or following high spinal anesthesia the patient's head should be lowered to the Trendelenburg position in addition to the other measures suggested.

XL. ANESTHESIA

GENERAL ANESTHESIA

The administration of anesthesia is an exacting medical procedure. In no other act are the patient's life and welfare so immediately and exactly controlled and manipulated. No other diagnoses must be more exact than the minute to minute diagnoses during anesthesia. No other drugs are given to such exact physiologic limits as are anesthetics; no other must be given taken away or antidoted so precisely.

General Considerations—Analgesia is the absence of the sensation of pain; anesthesia is the absence of all sensation while general anesthesia is the absence of sensation throughout the entire body accompanied by unconsciousness. These effects are brought about by the action of certain agents on the nervous system. The special characteristics of nerve cells are irritability and conductivity. Conditions such as lack of blood supply or lack of oxygen and agents such as pressure, heat, cold, and anesthetic drugs reduce or abolish irritability and conductivity. Some authorities state that whatever the agent, anesthesia is accomplished (i. e. irritability and conductivity are abolished) by keeping the requisite amount of oxygen out of the nerve cell. The term anesthesia does not fully describe the effect produced by anesthetic agents. Not only are sensation and consciousness abolished but frequently the efferent paths also are paralyzed, suspending the function of glands and muscles. Anesthesia then denotes the induced loss of irritability and conductivity with insensibility, inhibition or paralysis in any part of the nervous system, afferent, central or efferent. Tone or tonicity is, according to Stedman, a state of normal elastic tension of the tissues by virtue of which the parts are kept in shape and as it were alert and ready to function in response to a suitable stimulus. Tone is present as long as the efferent nerve path is normal, even though unstimulated. Tone is abolished if the efferent nerve path is entirely deprived of its irritability and conduc-

tivity. Surgical anesthesia is loss of sensation with mental and muscular relaxation sufficient to permit operative work.

In general anesthesia the agent or agents are brought into contact with the nervous system through the blood stream. Approaches to the blood stream in the order of their rapidity are as follows: intravenously by inhalation, subcutaneously by colonic absorption and by stomach. Each anesthetic on account of its physical and chemical properties is suitable only for certain avenues of introduction. When distributed by the blood stream the drug is present in all the tissues of the body in approximately the same concentration but is manifested principally in the nervous system. The various parts of the nervous system are not equally affected by the same concentration of an anesthetic. In general those parts which are newer in evolution and less necessary for the maintenance of life are more easily affected by weaker concentration while those parts which are older and more necessary for life require stronger concentrations to affect them. This rule is not at all invariable. Certain anesthetics affect certain nerve elements differently in point of sequence and degree. Nevertheless, the parts of the nervous system succumb to all anesthetics in sufficiently regular sequence so that this sequence may be used as an index of the stages into which anesthesia is divided. Each stage of anesthesia represents diminution of irritability and conductivity, i. e. the inhibition or paralysis of certain parts of the nervous system.

As the concentration of the anesthetic in the blood stream and in the tissues is increased from nothing to the lethal dose, the parts of the nervous system are inhibited and paralyzed in approximately the following order:

- 1 The higher centers. Inhibitions, orientation, emotions, memory, will, sensation, consciousness.
- 2 The spinal and cranial nerve reflexes.

From the clinical evidence it would seem that these are blocked by anesthetizing one or more neurons on the sensory side of the arc

- a The reflexes from the periphery through the brain stem or spinal cord to the voluntary muscles including the respiratory muscles
- b The reflexes from the periphery through the spinal cord to the sympathetic (thoracolumbar autonomic) system
- 3 The efferent or motor neurons to most voluntary muscles
- 4 a The parasympathetic (craniosacral autonomic) system
- b The vasomotor center
- c The respiratory center

Stages of Anesthesia—Anesthesia is described in four stages corresponding to the parts of the nervous system affected

First Stage Induction Analgesia—This stage is entered as soon as the administration begins. It is characterized by waning sensation and consciousness. As this stage progresses the inhibitions, orientation, emotions, memory, will, sensation and consciousness wane and disappear in approximately the order named. Sensation may begin to wane from the very first but may not entirely disappear until just before unconsciousness, thus giving a considerable period of analgesia.

Second Stage Light Anesthesia—This stage is entered when consciousness has completely gone. It is characterized by unconsciousness with remaining activity of the sympathetic reflexes and the voluntary muscle reflexes including those of the respiratory muscles. As this stage progresses the sensory or afferent neurons become increasingly anesthetized so that the reflexes diminish. The muscles remain in tone.

Third Stage Surgical Anesthesia—This stage is entered when the sympathetic and voluntary muscle reflexes including the respiratory have disappeared. It is characterized by unconsciousness and absence of reflexes; that is stimulation may be applied to any field without evoking a sympathetic, muscular or respiratory response. If a motor nerve is directly stimulated however the corresponding muscles contract. As this

stage progresses the motor or efferent neurons apparently become progressively anesthetized so that the chest muscles move less and less in respiration until they cease and the tone of the abdominal and skeletal muscles diminishes, relaxation becoming more and more complete.

Fourth Stage Overdose—This stage is entered when the parasympathetics and the vasomotor and respiratory centers especially the last become paralyzed. It is characterized by unconsciousness, absence of reflexes, great relaxation and failing centers.

Signs of Anesthesia—The signs of anesthesia are the physical evidences which denote the activity, inhibition or paralysis of the various parts of the nervous system. For convenience in observation the signs of anesthesia are grouped as follows: (1) sensory signs, (2) motor or muscular signs, (3) respiratory signs, (4) eye signs and (5) circulatory signs.

Sensory Signs—Sensation is present in diminishing degree during the first stage only. Consciousness, discomfort due to the inhalation of the anesthetic is shown by holding the breath, repeated swallowing, clearing the throat, vocally protesting, and moving the head or other parts of the body. Discomfort due to the operative preparation is usually shown by speaking or struggling.

MOTOR OR MUSCULAR SIGNS—First Stage—During this stage the voluntary muscles are all activated by both the will and the reflex stimulation. As this stage progresses the will becomes anesthetized and the muscles can be voluntarily moved less and less. The voluntary muscle reflex arcs are still active and any muscles may contract in response to sensory stimulation applied to any region of the body.

Second Stage—The will has been anesthetized. Voluntary movement has been abolished. The voluntary muscle reflex arcs are still active and any muscles may contract in response to sensory stimulation anywhere in the body. The eyelids resist opening. The eyeballs are widely moving or widely eccentric, especially in response to sensory stimulation and even in a remote area. The jaws resist opening. The arm and leg resist falling if lifted and dropped. The abdominal muscles are rigid. They resist retraction and tend to extrude the viscera.

if the abdomen is open. As this stage progresses the reflex responses become less and less.

Third Stage Four Planes A, B, C, and D

The afferent side of the voluntary muscle reflex arcs has been anesthetized and the muscles do not respond to sensory stimulation. *Plane A* The eyelids may be opened without resistance. The eyeballs are slightly moving or eccentric. The jaws may be opened without resistance. The mandible may even open and recede spontaneously by its own weight and thus obstruct respiration. The arm and leg fall without resistance if lifted and dropped. The muscles are still in tone and fairly firm especially those of the abdomen, so that with the abdomen open the viscera are somewhat under pressure and tend to escape. The muscles, however, do not contract in response to retraction or other stimulation. *Plane B* The eyeballs are fixed in the center looking straight forward parallel to each other. The muscles are less firm. *Plane C* The motor neurons are apparently becoming anesthetized; the muscle tone is definitely diminishing and the muscles are becoming more and more flaccid, allowing free retraction and stretching. *Plane D* The voluntary motor or efferent pathways have become anesthetized, and the muscles are flaccid.

Fourth Stage—Flaccidity remains

RESPIRATORY SIGNS—In the administration of an anesthetic all the factors which influence respiration are being constantly manipulated.

Respiration is modified by the will and the reflexes but is carried on by the respiratory center. The latter regulates respiration as to keep the diffusion pressure of oxygen and the pH of the blood at practically constant levels. A beginning lack of oxygen through its effect upon the carotid body stimulates the center to produce more rapid respiration in an effort to acquire more oxygen. Carbon dioxide produced from the consumed oxygen at a practically constant rate during anesthesia accumulates and lowers the pH to the stimulating point at regular intervals thus initiating succeeding cycles of respiration which in turn reduce the carbon dioxide content of the blood. Increased retention of carbon dioxide stimulates the respiratory center to produce first increased amplitude then also an increased rate of respiration in an effort to excrete the excess carbon dioxide. Increased pressure of gas into the lung causes greater expansion and requires greater stimulation by carbon dioxide and the Hering-Breuer² reflex and thus a greater excitement of the respiratory center to accomplish respiration. Obstruc-

tion brings the same result. All these factors stimulate the respiratory center, but if the stimulated effort continues too long and especially if it is unavailing in restoring the oxygen and carbon dioxide to the normal levels the respiratory center becomes fatigued and damaged.

In addition to the constant manipulation of these factors the dose of the anesthetic is being administered and regulated. Primarily the dose of the anesthetic determines the stage of anesthesia and the character of the respiration which indicates the stage and results from it. It must also be constantly remembered that the other factors which fatigue and damage the respiratory apparatus namely continued excess resistance or obstruction to respiration, continued excess carbon dioxide and especially continued and excessive oxygen lack add to and also themselves produce an anesthesia rapidly advancing to death. An uncorrected oxygen lack is especially damaging. If the rapid respiration of early oxygen lack fails to restore the oxygen but succeeds in washing out the carbon dioxide then respiration decreases because it is both paralyzed and unstimulated and anoxemia becomes immediately overwhelming.

First Stage Induction—During this stage respiration is carried on by the respiratory center but is modified by the will and the reflexes. As this stage progresses, the will becomes anesthetized and respiration is changed voluntarily less and less. The reflex arcs however, are still active and in response to stimulation applied anywhere in the body, any type of change or irregularity in respiration may take place. Holding the breath and straining on expiration are the two most common responses but any change in rate, rhythm, amplitude or force may occur.

Second Stage—When the second stage is entered, the will has been anesthetized. There is no voluntary change in respiration. The reflex arcs are active and may cause any type of change in respiration as just described for the first stage. As this stage progresses the afferent side of the reflex arcs becomes more and more anesthetized and reflex response in respiration becomes less and less.

Third Stage Four Planes A, B, C, D—

When the third stage is entered, the will is anesthetized. The afferent side of the reflex arcs has become anesthetized, and no reflex irregularity in respiration takes place. The respiratory center and the efferent paths to the respiratory muscles are still active. *Plane A* Third stage breathing, as carried on by the respiratory center mechanism in

hampered is like the swing of a pendulum—regular rhythmic automatic Inspiration and expiration are equal to each other in time amplitude and force. There is no pause between and each shades into the other *Plane B* Respiration is the same in character as in plane A but usually a little deeper and more stertorous because there is more general relaxation of the muscles of the throat neck and trunk *Plane C* As this plane progresses the efferent neurons to the intercostal muscles apparently become more and more anesthetized so that the chest excursion lags more and more behind the diaphragm in point of time and becomes less and less in amplitude. The movement of the diaphragm however being the last defense outpost remains unimpaired *Plane D* The will the reflexes and the efferent paths to the intercostal muscles have all been anesthetized. The chest does not expand at all with inspiration. In fact when the diaphragm descends the chest because of its complete relaxation may even be sucked inward. As this stage progresses the respiratory center and the efferent paths through the phrenic nerves to the diaphragm become increasingly anesthetized. The diaphragmatic excursion becomes reduced. As the center becomes less sensitive a greater fall in the pH is a greater accumulation of carbon dioxide is required to stimulate it. The interval therefore becomes longer. Inspiration becomes progressively shorter quicker more gasping in type. Expiration becomes progressively longer and less forceful followed by a progressively lengthening pause until respiration ceases. In cyclopropane anesthesia this type of depressed respiration does not occur but respiration remains regular and rhythmic gradually fading in amplitude until it ceases.

Fourth Stage—This period follows cessation of respiration while the heart is still beating and life still remains.

The signs consist in the changes in the behavior of the eyelids eyeballs pupils and lacrimal glands. The behavior of the lids and globes has already been described under the subject of muscular signs. The iris is composed of radial muscle fibers supplied by the sympathetic and circular fibers which in turn are supplied by the parasympathetic system. In addition to this there are radial

strands of elastic tissue. The lacrimal glands have a double innervation from both the sympathetic and the parasympathetic system. The sympathetic innervation produces tears in response to emotional and remote reflex stimulation while the parasympathetic reflex supplies the normal moisture and probably that excess needed to defend against foreign substances.

First Stage—The eyelids and globes move at will and in reflex response. The pupils may dilate and the eyes may be wet in response to fear or other emotion or in response to sensory reflex stimulation. According to Gellhorn³ Braunstein and Bain Irving and McSwiney⁴ dilatation of the pupils in response to pain is produced by inhibition of the parasympathetics rather than by stimulation of the sympathetic.

Second Stage—When this stage is entered the will has been anesthetized. The reflexes to the voluntary muscles and the sympathetic reflexes are still active. The lids may be rigid and the globes moving or eccentric. The pupils may be dilated and lacrimation may be excessive. All these signs are due to reflex stimulation and may be absent if there is no stimulation. As this stage progresses these effects become less and less. The light reflex is very active.

Third Stage Four Planes A B C D—When this stage is entered there is no voluntary movement. There is almost no reflex response by the globes. The sympathetic system has been anesthetized. The parasympathetic innervation is still in tone. In plane A the lids are relaxed the globes are slightly moving or eccentric and normally moist. The pupils are constricted. The light reflex is therefore not in evidence. As this stage progresses the voluntary muscles become more and more relaxed so that in planes B C and D the eyeballs are fixed in the center looking straight forward parallel to each other. In plane D the parasympathetic innervation becomes more and more anesthetized. The pupils become more and more dilated and the light reflex diminishes at the same rate until with large dilatation the light reflex is entirely abolished. The eyeballs become increasingly dry. With cyclopropane anesthesia the pupils in most cases do not dilate until respiration ceases and oxygen lack comes on.

CIRCULATORY SIGNS have a double significance. They help in indicating the stage of anesthesia and also indicate the vital condition, i. e. the ability of the patient to withstand the ordeal of the illness or injury, anesthesia and operation.

Cyanosis indicates lack of sufficient oxygen to charge all the hemoglobin to oxyhemoglobin. It may be local or general. For instance, with the Trendelenburg position the face may be somewhat dark because of slackened circulation there, although the rest of the blood may be normal. In a person who has ample hemoglobin slight cyanosis is easily seen, yet even with the hemoglobin unsaturated the vital centers may still be sufficiently supplied with oxygen. In a person who is anemic or in shock and therefore pale cyanosis is much less noticeable even though the vital centers may be actually suffering from a want of oxygen. With pallor cyanosis appears as a dirty gray and is of grave significance. Cyanosis then is a warning of oxygen lack. It should be heeded and the anesthetist should be still more alert for other circulatory or respiratory signs of oxygen want. Cyanosis is not however a dependable and final criterion. It sometimes may be considered necessary to carry plethoric persons in some degree of cyanosis in order to have them well anesthetized with a gas, the vital centers still showing no impairment, but the author believes that no cyanosis should be tolerated.

Pallor indicates anemia or shock. If this is due to an illness or injury before operation it presents an added risk and should be met if possible by suitable treatment before the onset of anesthesia and operation is undertaken. If pallor is noted during operation, it is due to hemorrhage or shock.

Pulse—A slow strong pulse indicates parasympathetic stimulation. A rapid strong pulse indicates sympathetic stimulation which may be caused by hyperthyroidism or by operative stimulation without sufficient anesthesia of the sympathetic nerves. A rapid weak pulse indicates debility, anemia, hemorrhage or shock before operation, hemorrhage or shock during operation or collapse of the vasomotor and cardiac centers due to overstimulation by operative manipulation under insufficient anesthetic or due to too much anesthetic, too little oxygen or a con-

tinued great excess of carbon dioxide. A slow weak or irregular pulse may occur as the terminal stage of the fast weak pulse or may occur primarily following an overdose of chloroform or cyclopropylane.

Cyclopropylane depresses the pre-motor and increases the irritability of the rest of the conduction mechanism. A concentration of cyclopropylane to which the individual heart is sensitive therefore causes slowing of the rate with the occurrence of auricular or ventricular extrasystoles which tend to merge into ventricular tachycardia and finally ventricular fibrillation. In the early stages this effect is easily reversible.

Blood Pressure—Increased blood pressure indicates sympathetic stimulation. This may be caused by (a) hyperthyroidism (b) operative stimulation without sufficient anesthesia of the sympathetic nerves (c) stimulation of the vasomotor center by moderate oxygen want or (d) stimulation of the vasomotor center by moderate excess of carbon dioxide. Decreased blood pressure may be caused by (a) preoperative debility, anemia, hemorrhage or shock (b) hemorrhage during operation (c) shock due to severe surgical trauma during operation (d) continued surgical manipulation with insufficient anesthesia fatiguing the sympathetic system and (e) collapse of the vasomotor and cardiac centers and perhaps the heart muscle due to too much anesthetic, too little oxygen or a continued great excess of carbon dioxide.

Preparation for General Anesthesia—No cathartic should be given but a plain enema the evening before is desirable if possible. Every effort should be made to promote the patient's confidence and to minimize the psychic trauma.

Preanesthetic Medication—**ANALGESIC** 1 F EFFECTIVE ADULT DOSES. Pentobarbital sodium $\frac{1}{2}$ grains one and one half hours before anesthesia. morphine sulfate $\frac{1}{4}$ grain plus atropine sulfate $\frac{1}{16}$ grain or scopolamine $\frac{1}{8}$ grain three fourths hour before anesthesia. This should be mercurial for especially large and vigorous adults and decreased for those who are small, frail, weak, debilitated, anemic or aged. For patients over sixty special care must be taken to estimate debility. For all adults the dose is varied according to variations from the

average size nutrition hemoglobin vigor etc

DOSAGE FOR CHILDREN The accompanying table is a good guide for children's preparatory medication. Traditionally children do not take morphine well. Practically the writer and many others have found that they take the doses cited very well and it is a great help in safe and smooth anesthetic

atropine, scopolamine or hyoscine, regard less of the time.

INTRAVENOUS ADMINISTRATION If sedation proves to be insufficient for satisfactory conduct of local or regional anesthesia or for smooth induction of general anesthesia it may be produced or fortified by morphine sulfate intravenously $\frac{1}{4}$ grain dissolved in 2 cc of water and injected very slowly until

TABLE 13.—PREANESTHETIC MEDICATION

Patient's Age Years	Patient's Weight Pounds	DRUGS AND DOSAGE ORDERED		SIMPLIFIED METHOD OF ADMINISTRATION PER HYPODERMIC		
		Morphine Sulfate Grains	Hyoscine Hydrobromide Grains	Tablets to Use	Preparation of Solution	Amount of Solution to Use Cc
Under 6 Mo	Under 15	None	$\frac{1}{16}$ o	1 tablet hyoscine hydrobromide gr $\frac{1}{400}$	Dissolve 1 tablet in 2 cc of sterile distilled water	0.5
6 to 11 Mo	21	None	$\frac{1}{1600}$			0.4
1 and 2	21-30	$\frac{1}{16}$ o	$\frac{1}{1600}$	1 tablet hyoscine hydrobromide gr $\frac{1}{400}$ plus	Dissolve both of these tablets in 2 cc of sterile distilled water	1.1
3 and 4	31-33	$\frac{1}{32}$ o	$\frac{1}{600}$	1 tablet of morphine sulfate gr $\frac{1}{16}$		0.5
5 and 6	39-46	$\frac{1}{16}$ o	$\frac{1}{600}$			0.7
7 and 8	47-55	$\frac{1}{16}$ o	$\frac{1}{600}$			0.8
9 and 10	56-63	$\frac{1}{16}$ o	$\frac{1}{400}$			1
11 and 12	64-78	$\frac{1}{16}$ o	$\frac{1}{400}$			1.1
13 and 14	79-100	$\frac{1}{16}$ o	$\frac{1}{500}$			1.3
15 and 16	100-140	$\frac{1}{16}$ o	$\frac{1}{400}$	1 tablet hyoscine hydrobromide gr $\frac{1}{400}$ plus	Dissolve both of these tablets in 2 cc of sterile distilled water	1.3
17 and 18	140-140	$\frac{1}{16}$ o	$\frac{1}{400}$	1 tablet of M.S. gr $\frac{1}{16}$		1.5
Over 18	140-160	$\frac{1}{16}$ o	$\frac{1}{400}$			2
Especially large and vigorous adults		$\frac{1}{4}$	$\frac{1}{16}$ o	11 lb gr $\frac{1}{150}$ MS gr $\frac{1}{16}$	2 cc	2

administration. Preparatory barbiturates should not be given with these doses. All preoperative hypodermic medication is to be given exactly forty five minutes before operation. If the child is especially vigorous or overdeveloped the dosage for the next older age group is given. If a child is debilitated, underweight, anemic or suffering from chronic illness the dosage for the next younger age group is given. A child should never be sent to the operating room without

the patient feels any one or more of the following symptoms: general warmth, slight dizziness, weakness or sleepiness, or tingling numbness or neuralgic discomfort in any extremity or in the back. Any discomfort will immediately cease. The patient will usually become quiet and remain quiet and cooperative. Too rapid injection may cause convulsions. Intravenous morphine sedation is excellent for bronchoscopy.

Care must be taken to remove from the

mouth false teeth chewing gum or any other foreign body before operation. The respiratory and pulse rates and the blood pressure should be recorded on the anesthesia chart before the anesthetic is started and frequently during the administration.

Anesthetic Agents—Discussion of the details of technique of the administration of various agents is not included in the scope of this article.

Ethyl ether was for over fifty years the most commonly used anesthetic. When not contraindicated it is still very generally used for operations requiring complete relaxation. It is administered by (a) the semi-open mask (b) oral insufflation (c) pharyngeal insufflation (d) intratracheal insufflation (e) vaporization with oxygen or one of the anesthetic gases or (f) colonic injection mixed with equal parts of olive or vegetable oil.

Diethyl ether ($C_4H_{10}O$) is a highly volatile liquid more potent and more rapid than ethyl ether which can be administered in all the ways suitable for ethyl ether. It is more pleasant for the patient and it is probably being increasingly employed. It is used on a very small and closely fitting mask to prevent excessive loss by vaporization. Its special field is for short procedures or for pleasant quick induction before ether is given especially for children. It produces any degree of anesthesia rapidly. Recovery is swiftly complete so that the patient can very soon go about his usual activity. Practically never is nausea produced. Most investigators have reported no damage to any tissues but some instances of hepatic damage have been noted after repeated or prolonged administration. Except for its inflammability it has taken away all need for using chloroform.

Chloroform is administered on the open mask. Because of its many good qualities it was once used very generally but because of the added immediate cardiac risk and danger of hepatic damage it is now little used except for certain cases in which a powerful and non inflammable agent is required as in malignant tumors of the head. Some surgeons insist on using it for convenience in obstetrical cases but this is a very questionable procedure.

Ethyl chloride on the open mask is very

pleasant and serviceable for short operations but it must be used with skill and caution and only by those who have had sufficient training. It tends to produce fatal spasticity of the respiratory muscles.

Nitrous oxide the first and weakest gas anesthetic is administered with just enough oxygen to supply the metabolic need and does not produce good surgical anesthesia unless the oxygen is reduced to or below the very margin of oxygen want. A little carbon dioxide may possibly be allowed to accumulate for respiratory stimulation and to combat the tendency to oxygen want.

Ethylene is a more powerful gas anesthetic and is given by the same technique. It produces somewhat more complete anesthesia with less limitation of oxygen.

*Cyclopropane*⁵⁻⁷ is a powerful gas which produces almost complete relaxation and is administered by mixing a small quantity from 5 to about 35 per cent of cyclopropane with 65 to 95 per cent of oxygen.

All gas anesthetics are best given by the completely closed method allowing as little escape of gas as is possible and absorbing with soda lime as much of the accumulating carbon dioxide as may be eliminated. Ether vapor may be added if sufficient relaxation is not otherwise obtainable. The administration of inhalation anesthetics through an intratracheal tube¹ provides entirely unobstructed respiration controlled ventilation improved relaxation and easy removal of bronchial secretion and is indispensable in certain operations on the chest neck and head. At the conclusion of inhalation anesthesia recovery is facilitated and nausea largely obviated by hyperventilation with oxygen. After this expansion of the lungs with air by means of moderate bag pressure helps to prevent atelectasis because nitrogen is much less quickly absorbed from the lungs than is oxygen. Instead of air helium with oxygen may be used with as good or better effect.

*Avertin*⁸ (tribromethanol) is given by colonic injection for basal anesthesia in a dose generally not to exceed 70 to 80 mg per kilogram of body weight and is then supplemented if necessary by nitrous oxide or chloroform by inhalation or by pentothal sodium intravenously for cautery operations. Avertin is very useful for thyroidectomies.

and for induction of anesthesia in apprehensive children. Many anesthetists are again using avertin for more complete anesthesia, judging the dose by the type of patient. The basal caloric requirement seems to be the best index of the required dose.

Sodium amytal^{10, 11} by intravenous injection has been used for general anesthesia in a dose of from 13 to 16 Gm in 20 cc of distilled water. The production of surgical anesthesia in this way has lost greatly in popularity largely because of the long time required for recovery and the untoward mental and nervous symptoms which too frequently follow so large a dose.

Pentobarbital sodium^{10, 11} (nembutal) in half the above dose produces equal anesthesia and less untoward after effects but has gained little popularity.

The two barbiturates just mentioned now find their most suitable intravenous use in prolonged or sustained control of severe convulsive states or intermittent control of intractable pain.

*Sodium etipan*⁹ or *etipal soluble* and *pentothal* (thiopentobarbital) *sodium*^{10, 11} are the latest barbiturate anesthetics and have become well established. They are given intravenously in 5 per cent or preferably 2.5 per cent solution slowly, about 1 cc each five seconds until the patient is unconscious and then 0.5 or 1 cc is added as needed to maintain anesthesia. Complete relaxation should not be sought as the respiratory center is thus endangered.

Pentothal sodium has proved to be so useful for such a wide variety of procedures that in some large hospitals it is used either alone or in combination with other anesthetics and methods in from 50 to 35 per cent of all cases. It is by far the most pleasant anesthetic available. The accepted duration of administration has gradually been increased up to two or three hours and it has been administered without detriment for as long as eight or nine hours. After a short period of anesthesia recovery takes place in fifteen or twenty minutes. After a long period recovery may require many hours with depression lasting long enough to increase the hazard of atelectasis. This is a serious disadvantage in pentothal sodium, a disadvantage which has prevented the use of intravenous anesthesia for major

surgical procedures in most hospitals. One of the best uses for intravenous anesthesia is to produce unconsciousness to supplement spinal anesthesia or nerve block.

Curare—The most spectacular advance in anesthesia in the last few years has been the use of curare to produce relaxation. A preparation of this drug is now available in sufficiently purified form to produce well controlled effects with apparently no harmful side effects. Patients may be carried under very light general anesthesia no deeper than plane A of the third stage and relaxation of any desired degree may be produced by the intravenous injection of 10 to 120 units of curare. The effect comes on in approximately one minute. A conservative dose should at first be injected and additional doses of 20 units should be injected at one minute intervals until the desired relaxation is produced. Various muscle groups are relaxed in the order of their susceptibility, the diaphragm being the last affected and the intercostals and abdominal muscles just before the diaphragm. If the diaphragm should be paralyzed artificial respiration by intermittent pressure upon the breathing bag is the only antidote necessary. Curare should never be given unless the anesthetist is certain that his mask fits properly; the patient's airway can be maintained and he can inflate the lungs by bag pressure. Prostigmine is the drug antidote but its use has never been found necessary by the writer. Cyclopropane is the best suited general anesthetic for combined use with curare but it may be used with others if the anesthetist is especially careful about the dose. Duration of curare effect varies from thirty to ninety minutes. It may then be repeated. One half to two thirds of the first dose is usually sufficient for the second dose.

Combined Anesthesia—The greatest characteristic of successful modern anesthesia is the combined use of different, perhaps several anesthetics and methods. Examples of this are the combined use of spinal and intravenous anesthesia, nerve block and intravenous anesthesia, intravenous induction followed by inhalation maintenance of anesthesia, intravenous induction of unconsciousness before the procedure of nerve block or spinal anesthesia and the combina-

tion of inhalation anesthesia of any type with the concurrent use of intravenous anesthesia. The use of combinations makes it possible to use a minimum of each drug with consequent rapid recovery. It is possible in this way to use each drug or method for its greatest advantage and not to call upon any of them for effects which can be produced only by a large dose.

Explosion Hazards.—Explosion may occur when a mixture of ether, ethylene or cyclopropane with nitrous oxide or oxygen is exposed to a flame or spark within the respiratory tract, breathing tubes or bag or tanks or within about 2 feet of any point of escape therefrom. Under certain special conditions the distance may be greater according to some authorities. The writer has never been able to collect an explosive sample of gas as far as 3 inches from the open end of the respiratory tubing with three times the customary amount of an explosive anesthetic mixture flowing from the machine.

The most effective prevention is (1) avoidance of static spark by having a relative humidity above 55 per cent, which continuously and equally grounds all persons and objects in the room and (2) keeping electric and hot instruments out of the chest and farther than 2 feet from the mask and apparatus. Anesthesia with CO₂ absorption and a completely closed respiratory circuit greatly reduces the hazard by providing adequate inside humidity and by minimizing the gas escape. Gas must be prevented from entering a tank containing another gas.

Metal or metal and water grounding of all objects in the room is effective against static but is practically impossible. Metal grounding of the machine alone is unwise in that it invites other objects and persons charged with static to spark against the patient, anesthetist and machine. Electrical instruments must not be used in the presence of metal grounding because of the danger of short circuits.

An intercoupler which equalizes the potentials of the patient, anesthetist, anesthesia machine and operating table is a wise provision.

Certain proportional mixtures of ethylene, cyclopropane and oxygen are non-inflammable and if accurately controlled mixtures of these three may be kept non-explosive and still may produce any plane of anesthesia. Dilution of cyclopropane-oxygen mixtures with helium or nitrogen in proper proportions also makes them non-explosive.

REGIONAL ANESTHESIA AND NERVE BLOCK

Never in history have so many surgical operations been performed under local, regional and spinal anesthesia as during these current days of World War II. The exigencies of battle, ashore and afloat, and conditions of personnel and supply at base establishments have combined to favor widespread use of injection techniques. Former stages of experimentation, controversy and uncertainty prevalent until recent years have abruptly been set aside, leaving nerve blocking methods the procedure of clearcut choice for most military and a considerable proportion of civilian operations. Today operations by the hundred of thousands are routinely performed without resort to inhalation narcosis.

Advantages of Nerve Block.—Reasons for this preference for nerve block are numerous, only a few illustrations needing to be cited. 1 The conscious cooperation of the patient is retained, alertness being but slightly dulled through judicious use of premedication given to allay apprehension. It is highly advantageous that the patient be able to move a limb to breathe deeply or to cough at the direction of the surgeon. 2 The surgeon, if he so desires, can work without the aid of a special anesthetist, a consideration of moment in certain emergencies, either military or civil. 3 The airways remain patent and sensitive respiratory mucous membranes sustain no pathologic injury. 4 Medullary centers are protected. 5 Damage to liver, kidney and other vital organs is minimal. 6 The injurious inflow of noxious sensory stimuli from the periphery or operative site is cut off. This is not the case under inhalation or intravenous anesthesia, where the patient is rendered incapable of response while such a bombardment continues. 7 The patient often is able to walk from the surgical amphitheater and to help himself to take nourishment promptly to cooperate in the frequent postural changes important in the prevention of thrombosis and embolism. All in all, operations are shorn of much of the character of dreaded ordeals.

Historical.—The ability to block sensory stimuli at their seat of origin at the periphery began with the discovery by Carl Koller, a student of ophthalmology in Vienna on Sept 15 1884 that operations on the eye could be painlessly performed after topical applications of cocaine. The significance of this discovery was immediately recognized throughout the surgical world and rapid advances followed. American surgeons (Halsted Cushing Crile Matas) played an important role in bringing the advantages of the method to all departments of surgical work. The toxicity of cocaine however and its habit forming properties proved almost insurmountable difficulties in attempts to standardize this form of pain control. Only when Einhorn more than twenty years thereafter (1905) introduced novocain an anesthetic agent but one-seventh as toxic as cocaine was sound and permanent progress in this field made possible which led to the development of the more elaborate technical methods now in use. Simultaneous blockade of many large nerve trunks (paravertebral block) or of complete plexuses (brachial block cervical plexus block) and of entire regions of the body now had their advent.

In 1927 alcohol nerve block was introduced rendering pain-control permanent or semi-permanent when so desired depending on the strength of the solution employed. Therapeutic nerve block for intractable pain as in carcinoma and a wide variety of injection techniques for treatment followed and during this period rapid development of diagnostic nerve block and prognostic block was observed.

Stages of Development of Regional Anesthesia.—Seven distinct stages have marked the three-score years of development of regional anesthesia namely, the four just cited and three of more recent origin.

- 1 Discovery of the clinical use of cocaine (1884)
- 2 Introduction of novocain (1905), followed by that of other less toxic anesthetic agents
- 3 A phase of rapid extension of diagnostic therapeutic and prognostic nerve block (1910-1930)
- 4 Advent of alcohol nerve block (1927) for permanent or semi-permanent destruction of sensory fibers
- 5 Continuous nerve block wherein a weak solution of an anesthetic agent is applied for many hours even days while the injection needle catheter or cannula remains in situ. Thus child birth and operations of unusual length have been brought within the domain of regional nerve blocking techniques

6 The sixth stage is the current one of universal military acceptance and routine application.

7 There remains the seventh and final stage that of chemiophysiological isolation of individual nerve fibers and fibrils. It is seen that most of the peaks in progress coincided with the introduction of new drugs demonstrating the association and interdependence of surgical and of chemical and biochemical progress. New drugs are now appearing with selective affinities for exclusive or dominant action on individual components of the nerve bundles. Thus for example vasoconstrictive fibers and other autonomic and visceral motor fibers are beginning to be controlled by nerve block methods just as reliably as have purely sensory components hitherto. All parts and regions of the body are now within the domain of the injection methods under discussion.

SCOPE OF NERVE BLOCKING METHODS

It is readily apparent that regional anesthesia has long since outlived its original name. The terms anesthesia and analgesia no longer prove adequate to indicate the full scope of nerve blocking procedures. Regional anesthesia, within a short span of years has reached a point from which it sends ramifications into every branch of medicine and to each of the medical specialties and the role it plays in these several domains is not minor but one of ever increasing importance.

Diagnostic Nerve Block.—Diagnostic nerve block may be defined as nerve blockade for the purpose of differentiating one condition from another.

The impulses for pain iniliary colic for example are carried over the ninth intercostal nerves and their associated white rami communicantes while those of renal colic traverse the first lumbar nerves and those of angina pectoris travel over pathways between the second and sixth thoracic trunks thus by appropriate injections to block these impulses such as myocardial disease entities and syndromes may be identified and diagnoses facilitated. Another example of diagnostic block is to be found in the field of peripheral vascular disease. It was early noted that an area which had been rendered anesthetic through nerve block injections shows an increase in the skin temperature distal to the site of injection and as the study of vascular disease advanced it was proved that nerve block released the area concerned from vasoconstrictor control i.e. the sympathetic vasoconstrictor fibers were affected as well as the sensory nerve. It is now possible to differentiate vascular diseases which are primarily vasospastic such as Raynaud's disease from those which are primarily obliterative such as arteriosclerosis. In the entities of the former category release of vasoconstrictor action leads to marked elevation of the surface temperature within the affected part but in the presence of any organic narrowing of the vessel lumen the release of vasoconstriction is insufficient to restore circulatory efficiency to the normal range.

Prognostic Nerve Block.—Prognostic nerve block makes it possible to foretell the probable course of a disease and to forecast the results that will follow surgical treatment. The foregoing statements relative to peripheral vascular disease illustrate the possibilities of prognostic nerve block. It has been demonstrated that the alterations in circulatory efficiency that follow blockade of vasomotor pathways with local anesthetic solutions approximately parallel those to be expected from surgical destruction of the same pathways (sympathetic ganglionectomy or ramisection). The patient may

then be given an actual preoperative sample of the state that will be surgically produced.

Therapeutic Nerve Block—Therapeutic nerve block signifies temporary or permanent control of nerve impulses for purposes of treatment. Injections of sensory paths and nerve trunks may be made in the treatment of sciatica, tic douloureux, angina pectoris, incurable carcinoma and other painful states. Therapeutic nerve block for thrombophlebitis has also gained popularity. In fact many of the techniques originated to provide temporary insensitivity for the purpose of aiding surgical intervention have now come to be used for permanent insensitivity and to make surgical intervention needless.

The question has well been asked: When would dare predict the end results in the alleviation of human ills that will ultimately result from the deliberate control and conditioning of the multitudinous physiologic activities directly under the dominion of the numerous individual components of peripheral nerve bundles as new injectable agents of high selectivity continue to be advanced?

TECHNICAL APPLICATIONS

Needles **Syringes** **Solutions**—It is preferable to have needles of fine gauge and where necessary long enough so that the operator can feel the various layers and fascia traversed by the needle point. Some operators prefer to make the intradermal wheel with a sharp needle and use a rather blunt needle for deeper injection, feeling that there will be more resistance from the heavier tissues and that there will be less chance of entering a vessel. Any good syringe that is used equally in proportion to the gauge of the needle can be used, whether it has an automatic refill or must be detached from the needle to be refilled. Scrupulous care must be employed so that the correct solution is used for thorough accident, high concentrations of stock solutions, alcohol, boracic acid and oil or fluids have been injected at times with fatal results. In making an injection into the deeper tissues the needle should always be passed through an intradermal wheel. From five to ten minutes must be allowed between the time of injection and that for beginning the operation.

A Topical Anesthesia—*Definition*—Insensitivity produced by direct application of an anesthetic solution (1) to mucous membranes, (2) to serous surfaces or (3) into open wounds.

1 Mucous Membranes—Topical anesthesia is extensively used in the work of the

ophthalmologist, rhinolaryngologist, urologist and proctologist. The anesthetic agent is applied in the form of drops or sprays or by means of applicators or pledgets soaked in the solution, occasionally full strength crystals being used. Most operators use solutions such as pontocaine, butyn and nupercaine.

EYE—It has been found that 2 per cent solution of pontocaine or butyn gives sufficient insensitivity for the removal of a foreign body from the cornea, however other anesthetics in liquid or ointment form often produce sufficient anesthesia to allow surface operations. For the removal of a cataract or iridectomy each operator uses the anesthetic he has found most successful.

NOSE—Adequate anesthesia of the nasal mucosa is obtained by spraying or directly applying pontocaine or butyn solutions. Quite extensive procedures can be carried out by using this technique—turbineotomy, septum resections, etc.

PHARYNX AND LARYNX—The use of anesthesia here is to control local sensation and reflexes and is best done by either spraying the anesthetic directly onto the mucous membranes or by the use of anesthetic lozenges (numerous products are on the market which are manufactured by reputable firms). Lozenges used preceding gas triscope are of value.

URETHRA—Only the less toxic anesthetic agents should be used in the urethra and bladder because of rapidity of absorption from these surfaces causing toxic or allergic manifestations. Diothaine (5 per cent) or solutions of pontocaine or metycaine are suitable agents.

2 Serous Surfaces—Weak solutions of the less toxic anesthetic agents often produce insensitivity to the surfaces of joint and peritoneal and pleural cavities.

JOINTS—Orthopedic procedures such as arthrotomy, removal of loose cartilage, reduction of dislocations and brisement may be carried out with the aid of synovial distention with a weak anesthetic solution. When the joint is to be opened this anesthesia must of course be supplemented by infiltration of the overlying tissues.

3 Open Wounds—It is often possible to obtain satisfactory anesthesia within and immediately around an open wound by packing the wound loosely with gauze or cotton

moistened with a dilute solution of one of the effective topical anesthetics. There is danger in the abuse of this method since open vascular channels in the wound may allow rapid absorption of the drug with systemic toxic reactions. However pain and sensitiveness can be so easily reduced in this manner that it is a highly useful procedure in treating comparatively small accidental wounds.

B Local Anesthesia—Definition—Local anesthesia is localized insensitivity of the skin or mucous membrane produced by subsurface injection of an anesthetic solution. This is induced either for the removal of purely intracutaneous lesions such as nevi, papillomas and warts or to allow the making of an incision through the surface to give access to the deeper tissues. Local anesthesia is extensively used by the general practitioner, general surgeon and dermatologist who are enabled by this method to perform almost any operation either by nerve block or by infiltration.

The intradermal wheal is the basis of all local anesthetic injections. The finest intradermal needle (27 gauge) is attached to a syringe filled with 1 or 2 per cent solution of procaine and passed into the skin. A small wheal is raised. A proper wheal produces a "peau d'orange" or "pig skin" appearance. The anesthesia is instantaneous.

*Removing a Benign Cutaneous Lesion—*The base of the lesion is encircled by wheals which must include sufficient area to allow for wide excision and subsequent suturing of the skin margins.

C Field Block Anesthesia—Definition—Field block anesthesia is insensitivity produced by infiltration of the tissues adjacent to the proposed operative field through which pass the sensory nerves of the operative site en route to the spinal cord. This procedure resembles local infiltration in the manner in which it is performed but resembles nerve block in that it effects interruption of the sensory pathways central to rather than within the field of operation. Its advantages over local anesthesia are the lack of distortion of the tissues in the field of operation, the prolonged anesthesia (since none of the fluid escapes through the incision) and the requirement of far less anatomical knowledge than for nerve block. The technical difficulties in creating a diffuse

will of anesthesia are by no means as great as when the exact seat of an important nerve trunk must be located.

The method is used in the removal of sebaceous cysts, lipomas and other tumors and for surgical exposures in all parts of the body.

*Scalp—*All the sensory nerves supplying the scalp are situated within the subcutaneous tissues. Therefore the entire cranium and scalp can be anesthetized by a zone of infiltration encircling the head.

*Finger—*An encircling zone of field block anesthesia at the base of the finger allows the removal of a foreign body, an incision for drainage, amputation or any operation on the digit. Caution must be taken so as not to use too much solution and overdistend the tissues, especially if the solution contains adrenalin because of the danger of causing necrosis. Infiltration is not made in the web space. The use of adrenalin is not advised.

*Thoracic Wall—*In the removal of ribs for empyema or in performing other operations on the thoracic wall the desired area is widely blocked by infiltrating all the layers. Subcutaneous block in the lateral aspect of the chest wall does not always provide satisfactory anesthesia. This is because the lateral cutaneous branch of the thoracic nerve which accompanies each rib emerges from its deep situation at the side of the chest and becomes subcutaneous there. Therefore even though its point of emergence may be entirely encircled by a zone of infiltration the area within that zone may still be unanesthetized. Paravertebral nerve block may be necessary to provide anesthesia in this particular region.

*Abdominal Wall—*Field block of an entire half of the anterior abdominal wall may be obtained by infiltrating all the layers along the costal margin and thence downward to the crest of the ilium, thus blocking the seventh to eleventh intercostal and iliohypogastric and ilioinguinal nerves. Of ten partial blocking of either side of the abdominal wall depending upon where the incision is to be made is a valuable adjunct to gas anesthesia producing proper relaxation. This form of technique is routinely used by many surgeons.

*Fractures—*From 10 to 20 cc of a 1 or

and injection of 10 cc This may be given every hour for twelve to fourteen hours if needed

Midcaudal block is used for analgesia of the lower abdomen as in gynecologic surgery cesarean section and hernioplasty Here again an initial dose of 30 cc is given and after five minutes the sacral area is tested The patient is turned in the position required by the surgeon A second injection of 30 cc is made and the table is tilted with the head down 3 degrees This is also suitable for operations upon the lower extremities except that the head of the table is raised 5 degrees

High caudal anesthesia is produced by giving an additional 30 cc above that used in midcaudal block the anesthesia will reach as far as the clavicles or nipples

Supplementary Injections—To use continuous caudal anesthesia supplementary injections are needed every thirty or forty minutes when epinephrine is not used or every sixty to ninety minutes with epinephrine depending upon the necessity for the continuation of the analgesia

SPINAL ANESTHESIA

Spinal anesthesia has been a most valuable contribution to the practice of surgery but it is well to keep in mind that there are dangers attendant on its use just as there

are on the use of any anesthetic Failure to observe certain principles governing its employment will result disastrously The majority of deaths that have occurred have resulted through failure to observe certain fixed rules The student should study one method and master it just as with any other surgical procedure While several methods are now enjoying success the technique of volume control is safe and reliable if accurately followed

When novocain is introduced into the subdural space it bathes the intradural tissues and is quickly absorbed by the nerve roots thus blocking the passage of sensory and motor nerve stimuli The spinal nerve that supply motor stimulation to the sympathetic nerves by way of the white rami communicantes are paralyzed by its upward diffusion a fall in blood pressure occurs as a result of the vasodilation and is probably directly proportional to the extent of sympathetic paralysis which may be gauged by the height of the anesthesia The sensory fibers are more susceptible to the influence of novocain than are the motor fibers To combat the fall in blood pressure Labat Babcock and Vebrs advocate the Trendelenburg position which causes the blood to gravitate to the brain and prevents cerebral anemia This position tends to defer cardiac and respiratory failure, despite relaxation of the entire vascular system A fall in blood pressure may be prevented also by the administration of ephedrine prior to the spinal anesthesia Ephedrine is a peripheral acting vascular stimulant and properly administered maintains normal vascular tone despite the paralyzing effect of novocain on the vasomotor fibers in the anterior roots of the cord

It has been found possible to produce spinal anesthesia which can be fairly accurately controlled as to the height of the anesthesia The use of any foreign substance other than novocain in the spinal canal is not required The upward extension of anesthesia is directly proportional to the rapidity of diffusion of the novocain injected the volume of fluid injected and the specific gravity of the solution of novocain it is inversely proportional to the rate of fixation of novocain in nerve tissue It may be influenced by the position of the patient's

body when there exists a difference in specific gravity between the solution injected and the spinal fluid. When the specific gravity of the injected solution is heavier than that of the spinal fluid the Trendelenburg position assumed during or immediately after injection of novocain will accelerate the rate of upward diffusion while Fowler's position will retard it. The dosage of ephedrine is varied in direct proportion to the degree of vasodilatation expected. To be readily absorbed ephedrine should be injected into the interspinous muscles and it should be given five minutes preceding the introduction of novocain.

Technic—Important factors in the technique of volume control (Stout) are aspiration of accurately measured volumes of spinal fluid used as a solvent for graded doses of novocain and the re-injection of the solution of spinal fluid and novocain without loss at a constant measured rate. A 22 gauge non breakable spinal puncture needle is used. Multiple punctures and trauma of the cord should be avoided. Graphic records should be kept of the patient's general condition, the height and duration of anesthesia, the blood pressure, pulse rate, drug administration and so forth.

Preoperative preparation depends on the condition of the patient, the nature of the disease and the type and extent of the operation. Time permitting the patient receives in addition to the usual preoperative measures the following: $1\frac{1}{2}$ grains of nembutal by mouth one-half hour preoperatively, pantopon $\frac{1}{2}$ grain and scopolamine $\frac{1}{150}$ grain for the patient under fifty years of age and $\frac{1}{200}$ grain for the patient over fifty by hypodermic one hour before operation. The scopolamine may be omitted if the patient is calm and the operation not prolonged. These dosages of course are only the average. The importance of individualization of preoperative medication cannot be overstressed.

The blood pressure is recorded and the surgical field prepared and covered with a sterile towel. With the operating table level the patient is placed on his right side, back bowed out, knees up and neck flexed. His position should not be cramped but must be maintained by an assistant. The back is surgically prepared. Ephedrine is then ad-

ministered. The dosage of ephedrine depends on the amount of novocain to be used; it is recommended that 15 mg. be given for each 50 mg. of novocain but this may be altered to satisfy complicating conditions. Thus one hesitates to give ephedrine to a patient with hypertension or advanced arteriosclerosis.

A drop of 1 per cent solution of novocain injected intradermally over the second or third lumbar interspace will minimize the pain of spinal puncture and provide better cooperation. In this area the 22 gauge needle is inserted and carried through the interspinous ligament into the dural sac. This is recognized by a temporary snap and the subsequent lack of resistance.

With the needle in the subdural space the stylet is withdrawn and spinal fluid should flow. It may be necessary to readjust either the direction or the depth of the needle. The syringe is attached and the desired amount of spinal fluid aspirated. One cubic centimeter of spinal fluid for each 100 mg. of novocain used insures a 10 per cent solution; the concentration usually employed in the technique of volume control. (Some workers prefer a 5 to 7 per cent concentration.) The syringe is detached and the stylet replaced. A larger mixing needle is then attached to the syringe and its contents transferred to the ampule of novocain crystals (Metycaine, spinocaine, pontocaine and nupercaine have their advocates.) The dosage of novocain should not commonly exceed 200 mg. although 250 to 300 mg. is used routinely in some clinics for operations on the gallbladder and stomach. The crystals are dissolved by agitating the solution and at the expiration of five minutes from the time of the injection of ephedrine the stylet is removed and the novocain solution injected at the rate of 1 cc. in five seconds. The needle is then withdrawn, the site of puncture covered with sterile gauze and the patient quickly turned on his back.

The level of anesthesia is then carefully observed as it climbs upward. If it does not progress with sufficient rapidity the head of the table may be slightly lowered. As soon as the correct level of anesthesia is reached the table is leveled for ten minutes to assure fixation. While the patient is being draped the anesthetist should record the

blood pressure. The patient first experiences a sensation of warmth and tingling in the feet followed by numbness and inability to move the legs. Occasionally there is nausea due to the falling blood pressure. Adrenalin will often check this fall and then additional ephedrine may be used. Carbon dioxide usually controls the nausea. When the height of anesthesia is fixed the Trendelenburg position may be safely assumed and this likewise counteracts the tendency to nausea by preventing cerebral anemia.

The patient should at all times be under the care of a competent anesthetist who should be ready to administer carbon dioxide and oxygen at the patient's first sign of discomfort. Ampules of adrenalin, ephedrine and pantopon should be available for immediate use. Frequent blood pressure readings should be made. Several sterile sets for spinal anesthesia should always be available. The ampules of novocain crystals, ephedrine and adrenalin may be kept in covered cups containing 70 per cent alcohol.

In recent years in an effort to find a longer acting drug a number of substitutes for novocain have been perfected for use in spinal anesthesia. Pontocaine and nupercaine are the two best known of these preparations. The length of analgesia with pantocaine is about two hours and with nupercaine about three to four hours.

The stock 1 per cent solution of pontocaine has a specific gravity greater than that of spinal fluid therefore a technique similar to that used for novocain can be followed in its use as a spinal anesthetic. Two cubic centimeters of a 1 per cent solution is the maximum dose thus being mixed with an equal amount of spinal fluid and injected at the rate of 1 cc per twenty five seconds. Smaller amounts of ephedrine can be used as the fall in blood pressure is much less than with novocain. Pontocaine is fixed more slowly than novocain however and the patient should not be placed in the Trendelenburg position until at least twenty minutes has elapsed. Pontocaine is also put up in crystalloid form in 10 and 20 mg ampules. The same technique is used the crystals being dissolved in 2 or 4 cc of spinal fluid respectively.

Nupercaine solution 1:1500 has been used for spinal anesthesia when an even longer

duration of anesthesia was desired. Since this solution is lighter than spinal fluid an entirely different technique is used and to avoid confusion it will not be discussed here. Hadd and Sise have published an excellent article on nupercaine anesthesia in which the technique is carefully discussed.

It must be emphasized that both pontocaine and nupercaine are more toxic than novocain and should be used only by an experienced anesthetist and then only after a careful study of a technique applicable to their use has been made.

A recent development in spinal anesthesia namely the use of continuous or fractional spinal anesthesia eliminates to a large extent the need for the use of the more toxic longer acting anesthetic agents. In this technique a specially designed slotted matrix 5 inches thick and a very flexible special alloy lumbar puncture needle permit the returning of the needle in place in the subarachnoid space throughout the entire operation. The needle is connected to a syringe by means of a 30 inch piece of rubber tubing. Pontocaine previously mixed with spinal fluid to a 1 per cent strength that is 50 mg of the drug per 1 cc of spinal fluid is then injected in fractional doses as needed during the operation. By this method anesthesia can be continued indefinitely while under control at all times. Usually 300 to 500 mg of novocain dissolved in from 6 to 10 cc of spinal fluid is sufficient for most operations but as high as 2,200 mg has been used without untoward results.

Indications and Contraindications for Spinal Anesthesia.—Spinal anesthesia is especially indicated in all cases in which complete relaxation of the abdomen is desired. It should be used in preference to inhalation anesthesia in the presence of an infection of the upper respiratory tract unless specifically contraindicated and it may be used in most cases of major operations below the diaphragm in which it is safe to use inhalation anesthesia.

It was formerly believed that hypotension was a contraindication to the use of spinal anesthesia but careful building up of the blood pressure with ephedrine eliminates this factor. Neither is hypertension a contraindication *per se*. Spinal anesthesia should not be used in patients with severe myo-

cardial damage or advanced arteriosclerosis it is contraindicated in the presence of any disease of the central nervous system.

Complications.—The literature contains reports of various complications that have followed the use of spinal anesthesia but only 2 possible fatalities occurred in a series of over 4000 cases at the Jackson Clinic. One of the first patients had convulsions on the operating table and could have been saved with the present day knowledge of the proper technique. Headaches formerly a fairly frequent complication of spinal anesthesia were due to the large caliber of the needle used, traumatization of the cord and loss of fluid. Flexing the foot of the bed to prevent headaches is not required with the proper technique. However the patient should be required to lie flat in bed for twenty-four hours. The writer has observed no parestheses of more than a transitory status. Meningitis due to a contamination of the solutions, syringes or needles has been reported. The preoperative use of nembutal should obviate the possibility of convulsions resulting from the injection of novocain into the venous plexus around the cord. This danger can be further minimized by carefully observing the rule never to inject when a bloody tap is obtained, as this is always an indication for making a fresh spinal puncture.

Advantages and Disadvantages.—The advantages of spinal anesthesia may be gauged from the standpoint of the patient, surgeon, nursing staff and relatives. Many patients dread the thought of being put to sleep more than they fear the operation. Pain is usually eliminated as soon as the spinal anesthetic is administered yet the patient retains full consciousness. Postoperative nausea and vomiting are largely eliminated and distention is decreased. There is no damage to a normal cardiovascular or vascular system. There is little or no disturbance of the nervous system and the psychic factor of an operation is minimized for the average patient. The patient returns to the room cheerful and smiling and able to converse with relatives. Fluids may be taken before, during and after operation. There is no struggling on awakening, no retching or straining of the wound and consequent pain. There is no mucus to be aspirated. The pa-

tient can cooperate in preventing postoperative atelectasis by deep breathing and assisting in moving.

The advantages of spinal anesthesia to the surgeon may be summarized as follows. Relaxation of the abdominal wall largely eliminates the need of retraction and of wadding off the intestines and permits better exposure of the operative field. The intestines remain in a contracted quiescent state enabling the source of trouble to be more quickly located and alleviated. The time element is further reduced by the ease of closure due to the relaxation of the abdominal wall. The patient can cooperate with the surgeon, a condition which cannot be obtained under a general anesthesia. The surgeon may converse with the patient if necessary.

The advantages to the nursing staff are innumerable. The use of emesis basins and the constant care of the patient after he is returned to his room after a general anesthetic are largely eliminated. The patient is able to cooperate with the nursing staff. The moaning and groaning that disturbs the morale of every one in the hospital is avoided.

The disadvantages of spinal anesthesia are that (1) the operating time is limited unless supplementary inhalation anesthesia or the continuous spinal method is employed; (2) it requires the services of one thoroughly conversant with the technique of its administration and the physiology of its effect on the central nervous system; and (3) it is not a satisfactory anesthesia for little children because of the difficulty of securing a child's cooperation during the administration of the anesthetic.

Caudal anesthesia should be mentioned as a type of spinal anesthesia. It consists in passing a needle through the sacral hiatus and depositing an anesthetic fluid within the sacral canal. The solution is distributed outside the dura mater and the process is thus differentiated from ordinary spinal anesthesia in which the anesthetic agent is introduced into the subarachnoid space. It may be used in a single injection technique or in the continuous manner as popularized lately for use in obstetrics.

XLI. PREOPERATIVE AND POSTOPERATIVE CARE

GENERAL PRINCIPLES OF PRE OPERATIVE TREATMENT

In discussing briefly the preoperative preparation of the patient it is possible to deal only in rather wide generalizations. It is obvious that conditions may radically alter or modify subtract from or add to any course of procedure that might be pronounced as a routine method. One need only pause to think of the multitude of factors which may have to be met to realize the complexity of the undertaking. Is the patient young or old thin or fat male or female nervous or phlegmatic sane or insane? Is there a complicating lesion—cardiac pulmonary vascular renal hepatic pancreatic? Does the contemplated surgical operation carry with it the necessity for any special preparations such as is frequently the case with operations on the thyroid thoracic cavity stomach or bowel? Does the anesthetic agent chosen demand preparatory measures? This list scarcely scratches the surface of the multitudinous questions which present themselves to the conscientious surgeon in the preparation of any patient for the ordeal of any operation how ever simple. Certain risks and responsibilities must be shouldered by him owing to the nature of his calling but he is not playing fair with the patient or with himself if he does not make every possible effort to reduce these hazards to the absolute minimum before the operation. This then is the goal of all preparatory procedures.

It is most essential that the surgeon should have the complete confidence of the patient in order to obtain absolute cooperation. It is a most difficult if not impossible task to cure a patient *in spite of himself*. To that end it is important to take enough time to talk things over with the patient and the family beforehand—the reasons for the operation its gravity and expected outcome even any unusual or salient points in the preparation for or care after the operation. In this way a mutual understanding is es-

tablished which later may be of invaluable assistance to the surgeon. Not infrequently certain individual characteristics of that particular patient may be discovered which will be of vital assistance or importance in the later handling of the case. Conversely many unpleasant situations due to misunderstanding of motives or principles may be avoided. It is essential for the surgeon really to know his patient and to give the patient an opportunity in turn to know the surgeon. In this way the patient is put in the proper frame of mind for the operation and *every thing* after that is much simpler and easier.

A carefully taken detailed history both past and present is of the utmost importance even though it may at times seem rather inconsequential or irrelevant. Occasionally something of great value is discovered and it is this occasional finding that makes it worth while to bend every effort to disclose it. A sensitivity to some common drug a hemophilic tendency or a functional organic defect physically not detectable may be brought to light which would otherwise escape detection and might subsequently mean defeat to the surgeon and disaster to the patient. There is too common a tendency to slur over this safeguard in the apparently simple case and particularly in the emergency case. It is true that there are times when a detailed history should and must be omitted but such instances are actually very rare.

A systematic complete *physical examination* supplemented by such clinical tests—chemical laboratory roentgenographic mechanical—as may be indicated or deemed advisable falls in the same category as the aforementioned history but is if anything even more important. Many extraneous complicating factors are picked up in the course of even the most perfunctory physical examinations (many others would be were the examinations adequately and intelligently performed) which may modify or alter completely the further handling of the case preoperative operative and post-

operative Is the surgeon fair to himself or his patient in ignoring or skipping these important preliminaries?

If during the preliminary examinations some complicating factor is discovered this should as a rule and as far as possible be corrected compensated or planned for before the operation. So the weak or failing myocardium should be digitalized the damaged or insufficient kidneys stimulated the hyperthyroid patient adequately iodized and the diabetic stabilized. It is here particularly that an understanding cooperation between the surgeon and internist is of the greatest importance and help to the patient. But these conditions will be more fully dealt with elsewhere and cannot be detailed here. Instead only the average normal case if there be such a phenomenon is to be considered here.

It is in the young and the aged that the greatest care must be taken to maintain the fluid and alkaline reserve level of the body. A relatively small amount of vomiting such as occurs in a case of acute appendicitis or strangulated hernia may produce appreciable dehydration and incipient if not actual acidosis together with lowering of the chloride value beyond the desired limits. In the average young or middle aged adult this is more difficult of accomplishment. Whenever such a depletion is present it should be corrected by the administration of fluids and alkalis or sugars together with the necessary chlorides. The administration is effected by mouth if the vomiting has ceased and such administration is not otherwise contraindicated by rectum if tolerated and absorbed either in continuous drip or small retention enemas by subcutaneous infusion if the tissues will take it up properly or intravenously which is possibly the best and certainly the quickest and surest way of all either in bulk dosage or continuously by drip through a previously inserted cannula. If sugars are given in any considerable quantity in this way the advisability should be considered of partially balancing it with insulin.

In almost every operative case which is not an emergency with the time for preparation hence limited it is probably wise to augment the glycogen reserve of the liver by administration of sugars for twenty four

hours or so before the operation. This may be done by mouth or intravenously. It seems particularly valuable in surgical treatment of the gallbladder.

When there is any marked anemia either primary or secondary a transfusion is usually indicated. The operative mortality the occurrence and degree of postoperative shock and the incidence of postoperative complications seem to bear a more or less direct ratio to the degree of anemia. For this reason one should hesitate to operate on any patient with a hemoglobin content below 60 per cent. If an operation is to be performed which promises to be of considerable magnitude or if there will probably be a considerable loss of blood it is wise to have the patient's blood grouped and matched before operation and have a suitable donor available. It is certain that some transfusions thus be easily averted by taking these extra precautions.

If the patient is jaundiced or has any natural or acquired tendency toward uncontrolled or abnormal bleeding tests for bleeding and clotting time should be made and every effort exerted to bring the values within normal limits.

Finally there are certain routine preparatory measures which apply to virtually all surgical cases. If the stomach, bladder and bowel are empty there will be less difficulty with the anesthetic and less postoperative discomfort. If possible the patient should be given a relatively simple diet of easily digested food the day before operation with nothing but liquids for the last twelve hours and not even these during the four hours before operation. If an emergency operation is to be performed and the patient has eaten within six hours it is usually wise either to induce vomiting or to wash the stomach out before an anesthetic is administered, thus at least to a certain extent removing the danger of aspiration of stomach contents. The anesthesiologist in particular will be grateful. If a cathartic is given it should be one with a quick and thorough action and should be administered at least twenty four hours beforehand. In any event it is wise to give an enema—warm soap suds is the simplest and as good as any—either the night before or early on the morning of the scheduled operation. This is particularly im-

portant in order to obtain proper retention and absorption when any anesthetic such as avertin is to be administered rectally.

The matter of preoperative sedation especially in the nervous or apprehensive patient depends somewhat on the choice of the anesthetic agent to be employed. Various barbiturates notably luminal sodium luminal amylal sodium amylal nembutal and so on usually in rather large broken doses either by mouth or intravenously are fairly widely used. Their greatest benefit is probably in dulling the sensibility of the patient who is to undergo local regional block paravertebral or intraspinal anesthetic. Morphine or hyoscyne or a mixture of the two is sometimes used similarly; the former may be used preparatory to an inhalation anesthesia but many anesthesiologists do not recommend this because of its tendency to induce slow and shallow respirations and to interfere with the pupillary reflexes. Possibly one of the best and safest methods is the administration of a small dose of avertin—*not* over 60 mg of the drug per kilogram of body weight—as a basal anesthetic. It should be administered while the patient is in bed in his own room about half an hour before operation. In this way the patient usually has no recollection of being taken to the operating room. Other good basal anesthetics that are now available are secobarbital administered by mouth and pentothal sodium administered intravenously. Lately they have somewhat replaced avertin in popularity.

If an inhalation anesthetic is to be administered and even in other cases a fairly large dose of atropine given hypodermically just before the patient is taken to the operating room is a great help in checking secretions and probably helps to reduce the number of postoperative pulmonary complications. (See section on Atelectasis.)

In the choice of anesthetic many factors need to be considered. Practically every hospital and surgeon has some definite routine or preference in the matter. It is impossible to discuss here the virtues or faults. One anesthetic may be preferable in one case and another under a different set of circumstances. However the *individual patient* should be considered primarily *each time* the choice of anesthetic is made and that

one should be used which seems the *safest* for that particular combination—nervous make up and general condition of the patient type of operation facilities at hand and the ability of the anesthetist.

The last step in the preparation of the patient is the cleansing of the field of operation. There are almost as many variations in this technique as there are hospitals and operators. The object in each case is the same—to render the field of operation as nearly sterile as possible. The most difficult structure to sterilize is the patient's skin and the ideally perfect method which has not as yet been evolved should sterilize not only the surface but the depths of the pores glands and hair follicles; it should not irritate or injure the skin mucous membrane or subcutaneous tissues; it should have lasting qualities of up to three hours; it should not interfere with wound healing and yet it should have sufficient simplicity and adaptability to be universally applicable and generally obtainable. The nearer these criteria are approached the better will be the results as measured in percentage of infected wounds. But here again there are certain underlying principles which apply irrespective of the specific technique. All hair should be removed with an adequate margin by careful shaving. All gross dirt should be removed with soap and warm water and the surface then dried. These two steps may best be done in the patient's room some time before the scheduled operation. The final preparation of the field in the operating room is discussed elsewhere.

MANAGEMENT OF THE SURGICAL DIABETIC PATIENT

The surgeon today is called on to perform many more operations on diabetic patients than formerly. The reasons for the greater frequency of surgical intervention are three: (1) the incidence of diabetes is increasing particularly among persons more than forty years of age; (2) the lives of persons affected with diabetes have been prolonged

as a result of modern methods of controlling the disease so that more of them are living long enough for conditions which require surgical treatment to develop or to be required and (3) many more elective surgical procedures can be carried out safely on diabetic patients than was formerly possible.

To illustrate the importance of this field of surgery from the standpoint of the number of operations performed on diabetic patients as well as to illustrate the low risk that may attend these operations there can be cited a series of 2607 operations of all kinds performed on diabetic patients at the Mayo Clinic in the ten year period from 1930 to 1939 inclusive. In this series there were 111 hospital deaths yielding a hospital mortality rate of 4.3 per cent. The operations included both major and minor procedures as commonly classified more than half of them being major operations such as amputations for gangrene, laparotomy for emergency abdominal conditions and so forth. Considering a specific operation, cholecystectomy for cholecystitis without any other procedure on the bile ducts it was found that among 109 diabetic patients who underwent this operation in the ten year period there were 2 hospital deaths giving a hospital death rate of 1.8 per cent. In 1939 among 703 similar patients who did not have diabetes there were 12 hospital deaths yielding a hospital mortality rate of 1.7 per cent or about the same as that recorded for diabetic patients. It is evident that the mortality of this type of surgical procedure among diabetic patients is not excessive. Diabetes can no longer be considered as ground for denying a patient the benefits of surgery and the decision to operate can now be based upon the same criteria among diabetic patients as among non-diabetic patients.

It is not to be forgotten however that the potential danger of surgical intervention in the presence of diabetes is as great as it ever was. The occurrence of acidosis and coma which often was unavoidable before the discovery of insulin is still a possibility which can be prevented only by the skillful employment of modern methods for maintaining normal metabolism. To this end the complete cooperation of the surgeon, the anesthetist, the internist, the dietitian and

the nursing staff is of the utmost importance. The patient should be subjected to a minimum of operative trauma, the period of anesthesia should be short and the preoperative and postoperative management of the diabetes should be precise. These recommendations apply to mild as well as to severe diabetes for mild diabetes temporarily may become severe subsequent to anesthesia and operation.

Preoperative Preparation.—Unless immediate operation is necessary the patient should be observed in the hospital for several days in order to secure the most favorable conditions. This period of observation is of particular importance when the diabetes is severe enough to necessitate the use of insulin. For two or three days before going to the operating room the patient should be completely free from acidosis, glycosuria should be well controlled and there should be adequate reserves of glycogen, water and electrolytes. The diet should be weighed and usually should contain 200 Gm. of carbohydrate. Under certain special conditions, notably surgical operation on the biliary tract and on the thyroid gland in the presence of hyperthyroidism, an even higher carbohydrate intake may be desirable. The caloric value of the diet of patients with hyperthyroidism should also be increased in proportion to the elevation of the basal metabolic rate. The qualitative character of the diet can be modified as necessary for patients who have lesions of the gastrointestinal tract provided its caloric and carbohydrate values are maintained at the desired levels. Sufficient insulin is used to maintain the urine free of sugar or nearly so. Other special aspects of preoperative preparation including medications are planned with regard to the general condition of the patient rather than to the presence of diabetes. On the morning of operation breakfast is withheld and a dose of protamine zinc insulin equal to approximately half of the total daily requirement of insulin is given.

Emergency Surgical Procedures.—Operations performed in the presence of diabetic acidosis or coma are done at greatly increased risk but to delay urgent surgical intervention may be even more perilous. This is particularly true when there are present

inflammatory lesions such as rapidly spreading gangrene of an extremity with infection acute appendicitis pelvic abscess mastoiditis or some other acute inflammatory process which if neglected may threaten the life of the patient as well as interfere with control of the diabetes. In such instances a single injection of 20 to 100 units of unmodified insulin depending on the degree of acidosis should be given 1 liter or more of physiologic saline solution should be administered intravenously and operation should then be performed without further delay.

Diagnosis of Abdominal Lesions—The diagnosis of acute abdominal lesions especially appendicitis may present serious difficulty in the presence of uncontrolled diabetes. The patient who has diabetic acidosis occasionally presents signs and symptoms closely resembling those resulting from lesions that require immediate surgical operation. Thus nausea and vomiting abdominal pain and tenderness rapid pulse leukocytosis and even fever may be associated with acidosis in the absence of any demonstrable abdominal lesion. Leukocyte counts as high as 60 000 in each cubic millimeter of blood have been observed during diabetic coma and counts of from 15 000 to 20 000 are not at all uncommon. Fever if present is due to infection or dehydration but the infection may be in the respiratory tract and not in the abdomen. On the other hand an acute inflammatory process in the abdomen may be associated with and responsible for the existing acidosis.

A carefully elicited history is of great importance in arriving at a diagnosis in such cases. Abdominal pain preceding the onset of other symptoms speaks for a surgical emergency particularly if the onset of the pain is acute whereas a gradual onset of symptoms with polyuria polydipsia and nausea preceding the abdominal pain probably means acidosis. Generalization of the findings on abdominal examination speaks for acidosis while localization usually indicates a surgical lesion. If pain persists after two to three hours of treatment of the acidosis surgical exploration of the abdomen should be carried out.

Anesthesia—Prior to the advent of insulin the choice of anesthesia was a matter of great importance. Inasmuch as there are

now good means at hand for the control of the metabolic disturbances produced by anesthesia provided the physician anticipates or recognizes them the patient can for the most part be placed under the kind of anesthesia which the surgeon ordinarily would choose for a non diabetic person undergoing the same type of operation. An anesthetic agent should be used which will produce a minimum of postoperative nausea and vomiting. From the standpoint of their effects on the carbohydrate metabolism of the diabetic patient the order of preference of anesthetic methods is approximately as follows: (1) local or block (2) spinal and (3) general. The order of preference of general anesthetic agents is approximately: (1) cyclopropane and oxygen (2) ethylene and oxygen (3) nitrous oxide and oxygen (4) intravenous pentothal or evipal and (5) ether. Local anesthesia and block anesthesia if they involve the use of considerable quantities of a vasoconstricting agent such as epinephrine may have an undesirable effect on diabetic metabolism by stimulating hepatic glycogenolysis. Obviously the same order of preference may not hold true from the standpoint of surgical indications. Ether for example causes loss of glycogen from the liver and acidosis but it may still be preferred when its use can be expected to shorten the time of operation and to reduce surgical trauma by providing better relaxation.

Postoperative Treatment—After operation the diabetic patient should be returned to a medical ward and the management of the diabetes should be the responsibility of a medical service. The essential features of treatment of diabetic patients during the first few days after an operation are sufficient fluids and electrolytes liberal amounts of carbohydrate and adequate insulin. Postoperative ketosis is common even among non-diabetic persons and when the patient is diabetic special precautions are necessary to prevent its occurrence. A daily intake of at least 120 Gm of carbohydrate should be maintained and the utilization of most of this amount should be assured by the proper administration of insulin. Slow intravenous injection of solutions containing 0.9 per cent of sodium chloride and 5 per cent of glucose will provide a satisfactory supply of fluid

which primary amputation was made through the leg secondary operation was necessary in only 4 cases and the ultimate outcome was fatal in only 7 per cent. In a more recent series of 66 primary major amputations among 61 patients Macey and Bickel reported a mortality rate of 10.6 per cent based on the number of primary amputations or 11.4 per cent based on the

diabetic patients with arteriosclerosis will burn and blister at temperatures far below those tolerated by patients who have a normal circulation. Within twenty-four hours after these measures are started the infection usually begins to subside or gives clear evidence of advancing. If it subsides treatment is continued until it is controlled fully and the decision then is made as to whether the

TABLE 15—RESULTS OF TREATMENT IN CASES OF DIABETIC GANGRENE OF TOES AND FEET*

	Patients†	Successful	Deaths	Mortality rate per cent
Treated medically	69	43	16	23.0
Treated surgically	86	71	8	9.3
Primary amputation below ankle (higher amputation later in 4 cases)	15	7	3	20.0
Primary amputation above ankle (higher amputation later in 4 cases)	71	62	5	7.0

* Data furnished by Allan and Kintner.

† All these patients had necrosis of tissue of considerable degree perforating ulcers and other sores were not included.

number of patients. Once amputation is decided on it should be performed below the knee if the pulsation is good in the popliteal artery, but above the knee if the pulsation is inadequate. McWhittrick and Root wisely advised against the use of a tourniquet in these amputations for pressure which is sufficient to shut off the blood stream in a calcified vessel may result in fresh thrombosis and subsequent occlusion. Also if a tourniquet is not used the amount of bleeding from an exploratory incision permits the surgeon to estimate the adequacy of the blood supply at the proposed level of amputation so that he can make the amputation higher if necessary.

The medical treatment in cases of infected extremities with or without gangrene includes absolute rest in bed, rigid control of glycosuria, application of warm moist dressings saturated with a mixture of equal parts of 50 per cent alcohol and a saturated solution of boric acid and chemotherapy with the sulfonamide drugs. The foot is very slightly elevated above the horizontal. The dressings should extend well beyond the region of infection and their temperature should not exceed 105° F (40.5° C), for the skin of

degree of accompanying gangrene or the degree of circulatory impairment justifies amputation. If the infection has progressed after twenty-four hours of treatment amputation usually is recommended. If redness and swelling extend beyond the ankle immediate amputation is urged. A gangrenous lesion which is dry and not grossly infected is covered with a dry dressing and protected against mechanical injury.

Measures for improving the collateral circulation in the feet should be used if it is decided that amputation can be delayed and if the area of gangrene is small enough so that there is reasonable hope of saving the extremity. These measures include postural exercises of the Buerger type which can be carried out by the patient himself or by means of a bed of the Sanders type and measures for producing vasodilatation such as contrast baths, the employment of intermittent venous occlusion, the ingestion of alcohol and an environmental temperature of about 86° F (30° C). The use of apparatus for producing alternate positive and negative pressure on an extremity is to be avoided as it is rarely beneficial and may result in extension of infection.

Ulcers and Other Sores—Lesions of the feet that are not accompanied by gross impairment of circulation are caused by a rule by injury and infection. They include infected corns and calluses, perforating ulcers, osteomyelitis, burns, frostbite, varicose ulcers and septic abrasions. The perforating ulcers and indeed many of the indolent infectious conditions of the feet in diabetes may in part be dependent on the presence of peripheral neuritis. Frequently the feet are abnormally insensitive and complaints of numbness and of aching pains at night are common. The insensitivity of such feet often leads to inadvertent injury. Woltman and Wilder have considered one reason for the neuritis of diabetes to be interference with the blood supply of the nerves. Osteomyelitis should be suspected in every localized infection of more than two weeks' duration in any part of a toe or foot (McKuttrick and Root). The diagnosis is made roentgenologically or by encountering rough bone with a probe on exploration. Amputation of a toe because of osteomyelitis when there is good pulsation in the dorsalis pedis and the posterior tibial arteries is a relatively safe procedure.

Often much needless suffering results from unnecessary delay in the treatment of minor injuries and infections of the feet. Diabetic patients should learn to take all abrasions seriously, to stay off their feet and to apply immediately a non-irritating antiseptic such as a mixture of boric acid and alcohol. Clean socks, well fitting shoes and avoidance of injury are important prophylactic measures.

The conservative treatment of chronic lesions of the feet is essentially the same as the medical treatment described in the section on gangrene. Thick calluses should be trimmed with a razor or filed down. The local application of sulfonamide compounds in powder form to chronic ulcers is helpful in some instances. The measures already mentioned for increasing the peripheral blood flow should be used if this is deficient. Extreme caution should be used in the application of heat or roentgen treatment to the feet of diabetic patients. Under no circumstances should hot water bottles or any other heating device which is not thermostatically controlled be applied below the knees. The temperature of solutions used in the prepara-

tion of wet dressings should be tested with a thermometer and should not exceed 103° F (40.5° C). Strict adherence to these rules will save many legs and obviate embarrassing medicolegal complications.

Fractures in Diabetes—It is generally recognized that diabetes is intensified and the requirement for insulin increased by infection by hyperthyroidism and by anesthesia and operation but it is not so well known that fractures may have this effect to a very marked degree. The following brief reports of cases provide illustrations. In one case a woman aged sixty-six years who had been known to have diabetes for five years sustained fractures of the surgical neck of the right humerus and of the right hip. Whereas the urine had previously been free of sugar without insulin for thirty days after the accident the patient required from 25 to 40 units of insulin daily. Another woman sixty years old who had had diabetes for four years sustained an intertrochanteric fracture of the femur. Before the fracture the insulin requirement had been 70 units daily; afterward a daily dose of 105 units did not completely prevent glycosuria. In another case a man forty years old sustained multiple fractures in an automobile accident. There had been no previous history of diabetes but immediately after the accident in tense glycosuria developed that required insulin for its control. On the one hundred and sixth day after admission a glucose tolerance test was carried out with practically normal results. The mechanisms by which fractures aggravate diabetes are not clear.

Carbuncles—This complication is nearly always preventable by cleanliness and proper attention to the control of glycosuria. Carbuncle has occurred in many cases of obese uncleanly patients who have given little care to their mild diabetes and who have made the mistake of squeezing or picking a pimple or boil. Since boils are sometimes due to infection from barbers' razors and since carbuncles may follow boils it is wise for the diabetic patient not to permit his neck to be shaved at a barber shop.

Deaths from carbuncle occur for the most part when treatment is delayed. In such cases the lesion may attain a large size and the fatal issue may be due to bacteremia. Early treatment of both the carbuncle and

the diabetes usually leads to a favorable outcome

There are wide differences of opinion and method in the treatment of carbuncle associated with diabetes but in general conservative measures seem to give the best results. The patient is kept at rest in bed and glycosuria is controlled rigidly. Thick gauze and cotton dressings saturated with a solution of boric acid and alcohol are applied to the lesion and kept warm. While no chemiotherapeutic agent can be expected to penetrate to the central region of destruction of tissue in a carbuncle early treatment with the sulfonamide compounds seems to be of real value in preventing further invasion of tissue and bacteremia. Sulfathiazole is the most logical of these agents because of its relatively low toxicity and its slight tendency to produce nausea and vomiting and because of its effectiveness against the staphylococcus which is the usual infecting organism in carbuncle. While chief reliance should be placed on oral administration local application of the compound in powder form also seems worth while. Treatment with roentgen rays may hasten localization of the infection and lessen pain.

Incision of a carbuncle if it is necessary at all is best done only after central necrosis has resulted in the formation of a well localized pocket of pus. Frequently the only intervention which is necessary to establish drainage is the gentle introduction and opening of a pair of sterile artery forceps. Occasionally the destruction of skin necessitates skin grafting but this is not the rule. A wide crucial incision extending through the zone of induration probably has led to extension of infection and bacteremia in some cases.

TRAUMATIC SHOCK

The word shock is applied to practically all types of acute peripheral circulatory failure regardless of cause or of multiplicity of causes. The grouping together under one term of a variety of conditions some of which have little relationship to one another, has made definition unsatisfactory and classification difficult. Attempts to substitute more exact terminology have resulted in failure. Just as there are many causes of fever so there are many causes of shock or acute peripheral circulatory failure. At least partial clarification would result from the use of descriptive terms in association with the word shock, such as shock following burns, shock following trauma to extremities, shock following hemorrhage and shock associated with peritonitis. It is important to remember that a number of different factors may be jointly responsible for the development of shock.

Many theories have been advanced in an effort to explain shock. The statements in the preceding paragraph demonstrate why no one of these has been accepted to the exclusion of all others. The three most generally accepted theories at the present time are (1) the theory of the regional loss of blood and fluid, (2) the toxic theory which includes the effects of bacterial infection and (3) the theory of the effects of trauma on the nervous system. It is the writer's opinion that the regional loss of blood and fluid at and near the sites of injury is the most frequent initiating cause of traumatic shock.

An attempt has been made to classify shock or acute peripheral circulatory failure from a physiological viewpoint. The terms which have been used to designate the different types are hematogenic, neurogenic

and vasogenic shock. These will be considered in order.

1 Hematogenic Shock—Hematogenic shock is the typical traumatic secondary or wound shock in which the important alteration is the reduction in blood volume. The output of the heart declines early but the arterial pressure may remain at or near a normal level as a result of compensatory vasoconstriction.

Since it is with this type of shock that this discussion is particularly concerned a statement of the present status of the problem is indicated. Increased confidence in the results of experimental observations has resulted from the finding of a close correspondence in circulatory changes in shock in man and in animals. It has been shown that a reduction in the volume of circulating blood is the most important factor in the initiation of shock. This reduction is due to the loss of blood or fluid at the site of injury, whether mechanical or thermal, and with the possible exception of the late stages of traumatic shock, there is no notable increase in capillary permeability in non-traumatized regions of the body. As shock progresses the cardiac output continues to decrease even though there may be no further reduction in the volume of circulating blood. After a critical point has been passed in diminishing cardiac output, lowered blood pressure and reduced blood volume, then progressive tissue anoxia leads to metabolic changes and to damage to certain organs such as the heart, brain and adrenals. This damage if prolonged constitutes the state termed *irreversible shock*.

While the reduction in blood volume is usually the main factor in the production of shock in injured persons, there is evidence that trauma to tissues adds considerably to the severity of the condition and in some instances may be the dominant factor. It is probable that products of tissue destruction enter the blood stream when the circulation is reestablished through partly devitalized tissues such as may be encountered in burns and in crushing injuries. In some patients who recover from the oligemic (reduced blood volume) shock of burns an illness of variable severity develops later. It seems probable that unknown factors in addition to regional loss of plasma are responsible

In crushing and compression injuries the satisfactory treatment of the early oligemic state may be followed some days later by development of renal failure. It is likely that the diffusible constituents of the injured tissues are responsible for the damage to the kidneys. Extensive bacterial infection when present in association with wounds and burns contributes to the development of shock. Severe injuries, particularly of the long bones, are followed infrequently by partial blocking of the pulmonary capillaries by globules of fat and by an unusual type of shock. In other words, in addition to the reduction in blood volume which is usually due to the regional loss of whole blood or plasma, there are these factors and others not mentioned which may play a part in the development of traumatic or hematogenic shock.

In addition to the variations in the underlying mechanisms which have been enumerated, it must be borne in mind that injuries to various parts of the body, such as the head, chest and extremities, may each have characteristic features.

2 Neurogenic Shock—Neurogenic shock refers to the condition in which vasodilatation occurs as a result of diminished constrictor tone. The blood pressure declines first and the reduction in cardiac output is subsequent. This type of shock may be due to direct action on the nervous system as by spinal anesthesia or it may be reflex in origin as from a severe blow on the abdomen. A decline in blood pressure of this nature is of less grave significance than that encountered in hematogenic shock, since it is not associated with such a serious decline in the blood volume. The observations of Phemister and others indicate that neurogenic elements are rarely of great importance in the pathogenesis of traumatic shock.

Considerable interest has been shown recently in a condition known as vasovagal collapse. It has been noted most often in blood donors, a small percentage of whom exhibit a slow pulse and profound collapse following removal of a pint or less of blood. It has been shown that this type of collapse results from sudden arteriolar dilatation and is apparently identical in mechanism with an ordinary faint.

3 Vasogenic Shock—Vasogenic shock

is the type in which vascular dilatation is brought about by direct action of substances on the vessel walls. Histamine probably produces its effects in this manner. Part of the effects of the passage of irritating intestinal juices into the peritoneal cavity is explainable on this basis.

It should be emphasized again that shock frequently represents a combination of several different types of disturbances.

Clinical Aspects—The clinical picture of fully developed traumatic shock is readily recognizable. Apathy, ashen cyanosis, clammy skin and low blood pressure are perhaps the outstanding characteristics. There is usually complaint of thirst. Nausea and vomiting are frequently present. Pain is not often a major complaint. The pulse rate is usually but not always elevated. There is generally a marked decrease in the volume of the pulse. The veins are not prominent. Alterations in respiration are much less obvious than those in the circulatory system. The urinary output is reduced. Hemoconcentration may or may not be present.

Difficulty arises in the recognition of early or incipient shock. This is unfortunate because shock can usually be prevented if early treatment is instituted. It has been stated that vasoconstriction functions to prevent a decline in blood pressure in incipient traumatic shock and hence alterations in blood pressure do not serve as an early criterion. Changes in the pulse rate may be misleading. Hemoconcentration is usually observed in association with burns, crush injuries and peritonitis but may not occur under other conditions. The response of the arterial pressure to an alteration of the position of the patient may serve as an early indication of shock.

Since there is no invariable early criterion of incipient traumatic shock, it is wise to assume that shock is impending and to institute treatment whenever the seriousness of the injury suggests that there has been extensive loss of blood or a reduction in volume of circulating blood from other causes. Examples of conditions which indicate that shock may be impending include blood-soaked clothing, signs of internal hemorrhage, extensive crushed areas, burns of large areas, lengthy operative procedures, severe

dehydration and prolonged exposure to cold. Inadequate nutrition, dehydration, exposure to excessive heat or cold, loss of sleep, physical and emotional exhaustion and various acute and chronic illnesses predispose to the development of shock.

Prevention and Treatment—In operations of election a great deal can be done to prevent shock. If dehydration exists the body fluids should be restored to normal. Drastic purgatives should not be given since they result in dehydration. Glycogen reserves in liver and muscle should be restored. Nervousness and fright should be overcome by sedatives and reassurance.

Hemostasis—Hemostasis should be as effective as possible. The quantity of blood that is lost during operative procedures is usually greater than the estimated amount. A tourniquet should not be used for the control of bleeding if other methods including pressure dressings will suffice. If a tourniquet is required, it should be released from time to time unless this procedure results in a prohibitive loss of blood. Cooling of the part distal to the tourniquet results in a lessening of the damage to tissues as a result of the ischemia.

Morphine—Morphine should be administered for the relief of severe pain but should not be given routinely. The majority of patients in a condition of shock do not complain of pain. Morphine causes nausea and vomiting in some patients and hence adds to the difficulty of preventing or treating dehydration. If morphine is given subcutaneously to a person in shock, it is well to remember that it may not be absorbed until the state of the circulation is improved. An additional injection then may result in overdosage.

Splinting—The immediate careful splinting of broken bones is of great importance. This measure reduces pain and lessens further damage to the soft tissues in the region of the fracture.

Posture—The posture of the patient is important. The head down or shock position usually results in subjective improvement. The head up position is often accompanied by a decline in blood pressure.

Temperature—In the past there has been too great emphasis on the desirability of causing elevation of the temperature of the patient in a state of shock. The temperature

of the extremities is decreased in traumatic shock because of the vasoconstriction associated with the lessened blood volume and because blood is diverted to more vital structures. If in the presence of an inadequate blood volume the extremities are surrounded by hot water bottles vasoconstriction is replaced by vasodilatation. Furthermore the loss of fluid by sweating results in further dehydration. An attempt usually should be made to conserve body heat rather than to add warmth artificially. If the patient has been seriously chilled he should be warmed slowly and cautiously. Plasma or blood should be available to be given promptly if the blood pressure falls during or soon after warming.

Adrenal Cortical Extract—Adrenal cortical extract has not been shown to have any effect on acute traumatic shock in man or animals in the absence of adrenal insufficiency.

Oxygen—Inhalation of oxygen in the treatment of traumatic shock has been disappointing. While in some instances the venous blood shows a substantial increase in oxygen content, usually no definite benefit is observed. When injury has led to interference with the respiratory oxygen uptake in wounds of the chest or in pulmonary edema from various causes it is obvious that oxygen therapy is indicated.

Vasoconstrictor Drugs—Vasoconstrictor drugs are rarely indicated in the treatment of traumatic shock since vasoconstriction is already present. The ideal to be sought is an increase in the blood volume rather than simply an elevation of the arterial pressure. If fluids are not available for replacement it is possible that one of the vasoconstrictor drugs may exert a temporary beneficial effect.

Transfusions—Just as the most important alteration in traumatic shock is the decrease in the blood volume so the most important form of therapy consists of methods which are directed to a return of the blood volume to normal. In some instances the major loss of fluid consists of whole blood whereas in others it is plasma. In the past the chief mistake has been an underestimation of the degree of fluid loss and of the quantity of fluid that is required to return the blood volume to normal. It has not been sufficiently

appreciated that the return of the arterial pressure to normal does not mean that the blood volume is similarly restored. Some patients may lose 25 per cent or more of the total blood volume without a significant reduction in the systolic pressure and it follows that the arterial pressure may return to normal after transfusion before the blood volume is fully restored. A patient who is in a state of severe shock is a result of hemorrhage usually requires a transfusion of 2 000 to 2 500 cc of blood.

One should not delay transfusions after hemorrhage until hemodilution occurs. The circulating hemoglobin is seldom reduced more than 15 per cent during the first several hours after hemorrhage regardless of its severity. The passage of fluids from the tissue spaces to the blood stream operates slowly in man. In other words hemoglobin levels during the early hours after injury do not serve as an adequate index of the severity of the blood loss.

In the absence of evidence of blast injury and pulmonary irritation the first 2 pints of blood or a blood derivative may be given as rapidly as 1 pint of isotonic fluid in ten minutes. Additional injections should be given more slowly.

The administration of blood plasma or serum is the ideal intravenous treatment for burns since it is mainly this part of the blood which is lost. Anemia may become a trouble some problem several days after the injury but is not in the beginning. If albumin concentrate is employed it should preferably be diluted with salt solution. The quantity of isotonic salt solution or of glucose solution which is injected intravenously should not exceed that of the blood or blood derivative which is used. Fluids should be given by other routes if they are retained and absorbed. Sodium lactate and salt solution by mouth and intravenously form valuable adjuncts in the treatment of burns but should not be used to the exclusion of blood derivatives such as plasma. There are a number of reasons why the use of sodium salts is beneficial. Recent work indicates that gelatin solution is a moderately effective substitute for blood plasma.

Since the loss of plasma during the early hours following a burn is so rapid it is more economical of plasma to space the injections

over a thirty six hour period than to give most of the solution during the initial period. Harkins and others have made a number of suggestions regarding methods for determining the requirements for plasma. One technique consists in giving 100 cc. of plasma for every point the hematocrit reading exceeds the normal level of 45. If hypoproteinemix exists a larger quantity is advisable. An alternative suggestion is that 50 cc. of plasma should be given for every point the hemoglobin reading is above the normal of 100. Still another method consists in gauging the therapy according to the area of body surface burned.

Renal Failure—In addition to preventing and treating shock which may ensue shortly after *crush injuries* one should employ measures to prevent delayed renal failure. The most important step is establishment and maintenance of an alkaline diuresis by the administration of sodium bicarbonate. Experience in England indicates that if possible fluid and alkali should be given to patients before release from compression.

Anesthesia—General anesthesia may add considerably to the severity of shock. It should be as light and as short in duration as possible. Ether by inhalation with a high concentration of oxygen, cyclopropane and ethylene are probably the safest agents when relaxation is needed. Local anesthesia should be used when it meets the requirements.

Operation—An attempt should be made to get the patient into a stabilized state before an operation is undertaken. This means among other things that operation must be delayed if alteration of the position of the patient has been accompanied by a fall in blood pressure. On the other hand operation should not be postponed any longer than is necessary. This is particularly important if there is continuing bleeding which cannot otherwise be arrested. Early operation is also important in preventing infection. Prior to the beginning of the procedure a needle should be placed in an accessible vein and blood should be administered throughout the operating period which preferably should not be prolonged beyond one hour.

Several points merit special emphasis. Much remains to be learned about traumatic shock, but it has been shown that in the ma-

jority of cases shock can be prevented or treated successfully by the early and copious use of transfusions of whole blood and blood derivatives. An attempt should be made to use in replacement therapy a solution of approximately the same composition as that which has been lost from the blood stream. The ready availability of plasma has resulted in its use in many instances in which whole blood is needed. Only red blood corpuscles can transport oxygen effectively. Blood or its derivatives should be administered according to the nature and extent of the injury and the blood loss. One should not delay treatment until the blood pressure declines or hemoconcentration or hemodilution occurs when it is obvious that the blood volume is decreased. Shock in association with an operation can usually be prevented by the administration of adequate quantities of blood during the procedure. Thus is expected and one is less apt to procrastinate if a needle is placed in an accessible vein prior to the beginning of an operation. The patient suffers as the result of the pride of the surgeon who is of the opinion that little blood is lost in procedures of the magnitude of thoracoplasty or pneumonectomy. A decline in blood pressure due to hemorrhage and associated with vasoconstriction requires rapid transfusion. A fall in blood pressure associated with vasodilatation is of less grave significance and the pressure will usually return to normal if manipulation is terminated. When in doubt transfusions should be administered. Furthermore care should be taken not to overheat the patient during or following operation.

ALFRED BLALOCK

ACIDOSIS AND ALKALOSIS

Acidosis and alkalosis are almost always associated with an altered water exchange. Abnormal losses of fluid by vomiting, diarrhea, drainage from intestinal and biliary fistulas or massive exudation from burned surfaces will withdraw water and the materials held in solution by it from the body until serious depletion of these substances may result. The loss is not only from the blood plasma but also from the other body fluids as water and materials are taken from them by way of the blood in response to the abnormal demand.

In order to understand the processes leading to acidosis and alkalosis a knowledge of the acid base composition of normal blood plasma is necessary and is shown in figure 762 (Gamble). For the sake of brevity only a few of the related facts can be emphasized. The predominance of sodium as the chief base and chloride ions as the chief acid radicals is important. It should be understood that the reaction of blood plasma and other body fluids is mainly determined by the ratio of carbonic acid to bicarbonate salt present in these fluids. This ratio is practically always such that blood plasma is alkaline but the degree of alkalinity may vary. The other inorganic substances present are salts of strong acids with strong bases and are therefore neutral salts. Another point of importance is that the number of acid radicals always equals the number of basic radicals. Adjustability is brought about mainly by the ease with which the bicarbonate ion can vary to fit the need being increased by formation from free carbonic acid or eliminated by again becoming free carbonic acid and being thus removed through the lungs. As the concentration of total base and of the stronger acid radicals may change importantly under abnormal circumstances the amount of bicarbonate ions present may vary from that producing an increased alkalinity of the blood plasma to the point of acidosis down to a decreased alkalinity described as acidosis.

Alkalosis.—Excessive vomiting is the most common cause of alkalosis. Vomitus contains an excess of chloride ions over sodium and the continuous withdrawal of these materials from the blood plasma in unequal portions results in a much larger deficit of chloride ions than of sodium. Bicarbonate ions are automatically increased to replace the lost chloride ions and thus cover the relative excess of sodium. If the degree of alkalosis produced is severe enough tremor of the facial muscles numbness of the extremities a positive Chvostek's sign and a carpopedal spasm may occur. It is certainly inadvisable to wait for the development of these signs in order to make the diagnosis of alkalosis. Whenever excessive vomiting occurs the condition should be considered and its presence and degree determined by a study of the chlorides of the

blood and the plasma carbon dioxide-combining power. The blood non protein nitrogen should also be determined to show the possible retention of waste products ordinarily excreted by the kidneys but now retained because the water usually available for renal function is lost in the vomiting.

The treatment of alkalosis consists of supplying sodium chloride and an abundance of water. The correction of the condition should be followed by studies of the blood chemistry. The salt can well be given as Ringer's or physiological saline solution. Although these solutions supply sodium and chloride ions in

Fig. 762.—The acid base composition of normal blood plasma

equal amounts and the patient has lost an excess of the latter the kidneys with a good supply of water can be relied on to excrete the surplus of sodium. The saline solution tends to be retained and is thus excellent for returning the lost electrolytes and water to the depleted tissues but for exactly that reason it is not ideal for furnishing an immediate excess of water. This can best be done by giving also a 5 per cent solution of glucose in distilled water. The glucose is rapidly oxidized and the water is left available for all physiologic purposes.

Acidosis.—The production of acidosis by an abnormal loss of intestinal secretions is

much less common among surgical patients than the production of alkalosis by vomiting. Intestinal secretions are alkaline and in contrast to gastric juice have a greater proportion of sodium ions than of chloride ions. In severe diarrhea or copious drainage from an intestinal or biliary fistula the continuous withdrawal of these electrolytes in unequal amounts from the blood plasma may result in a relative increase in chloride ions. A consequent reduction in bicarbonate occurs with the plasma reaction changing in the direction of acidity. The treatment of this type of acidosis is the same as that given for alkalosis. In this instance more sodium ions are needed than chloride ions but if salt is given with an abundance of water the kidneys will deal separately with these radicals and excrete the surplus. The extent of the acidosis and its correction should be determined by the same blood chemistry studies used for alkalosis.

Ketosis.—The accumulation of incompletely oxidized fatty acids in the form of beta-oxylutyric acid, diacetic acid and acetone is known as ketosis and is the most common cause of acidosis. These fatty acids displace bicarbonate ions with a consequent blood plasma reaction tending toward acidity. A reduction in the concentration of free carbonic acid in the plasma would help to correct this condition. An effort in this direction is made by the respiratory mechanism producing hyperpnea. This abnormal breathing, an acetone odor on the breath and ketone bodies in the urine are the clinical signs of ketosis. Ketosis develops when carbohydrate utilization is below metabolic needs as in starvation or diabetes mellitus. Immediate therapy consists in supplying glucose; insulin also is administered in the case of diabetes. The ketone acids are eliminated by proper oxidation processes and when there is an adequate supply of water by excretion through the kidneys. Since the fatty acids are neutralized in the plasma by base (sodium) and excreted by the kidneys with base, in severe ketosis there may be an important drainage of sodium from the body. In such cases the assistance of alkali therapy appears to be well founded.

While the foregoing brief discussions of alkalosis and ketosis have been offered sep-

arately, conditions may arise in which factors of both may be present at the same time. Extensive vomiting may deplete the blood chlorides and also by restricting the food intake may lower the carbohydrate metabolism with the resulting formation of ketone acids and acetone. Thus it is not uncommon to find patients with some degree of both alkalosis and ketosis. A plentiful supply of water and glucose and salt solution given in quantities checked by blood chemistry studies readily corrects the condition.

There are other causes of alkalosis and acidosis such as from therapeutic measures or in advanced renal disease but they are far less frequent than the instances presented.

WATER AND ELECTROLYTE BALANCE

Water is of greater importance to the human organism than any other substance. It normally comprises 65 per cent of the total body weight and is fundamentally involved in every physiologic process. After entering the body through the gastrointestinal tract, water passes to three compartments: the blood, the interstitial spaces and the cells. While there is no great reserve of any of these three, some water can be mobilized from the interstitial spaces. In health the normal balance is maintained in response to hunger and thirst. In sickness, because of the disease or the operation, the patient often cannot respond to these stimuli and the fluid intake must be provided for by the surgeon. A knowledge of the water requirements in health and disease is therefore fundamentally important.

There are two main sources of water available to the organism and three means of excretion as follows:

Ingestible water

- 1 Water drunk
- 2 Food, Diet or body substance
 - a Water content
 - b Water of oxidation

Excreted water

- 1 Water of urine
- 2 Water of stool
- 3 Water vaporized

The fluid intake varies from day to day with conditions of work, heat and humidity, but the amount usually ranges from 800 to 2000 cc daily. The water available from food comes from two sources, no matter whether the food used is that of the diet or of the person's own body substance. Usually the water content plus the water formed by the oxidation of food yields an amount of water equal to about nine tenths of the total weight of the food eaten. In this way the general hospital diet furnishes about 1200 cc of water a day, and the semi solid food of the soft diet about 500 cc.

Important water excretions are concerned with two physiologic processes, namely the dissipation of body heat by the vaporization of water from the skin and lungs and the excretion of waste materials in solution through the kidneys. The loss of water in the stool is rarely more than 200 cc daily, for although from 7 to 10 liters of fluid is poured into the upper part of the gastro intestinal tract each twenty four hours most of it is reabsorbed lower down.

The vaporization of water from the skin and lungs is an important part of the mechanism for the regulation of body temperature. It is continuous and relatively little affected by the supply of water available. Newburgh and his associates have shown that for a normal adult going about routine activities without sweating, vaporization accounts for approximately 25 per cent of the total heat dissipated and uses from 1000 to 1500 cc of water daily. With the sweating of hard physical work or of high temperatures and humidities up to 100 per cent of the body heat may be dispersed by this process and several liters of water may be so used daily.

In contrast to the vaporizing process the output of urine is markedly affected by the amount of water available, the waste materials presented to the kidneys being excreted

with the water left after the other processes have been cared for. There is a minimum of water needed, however, and even for a person with normal kidneys this should never be less than 500 cc daily. A volume of urine appreciably below this amount is insufficient and generally is accompanied by retention of waste materials, as shown by an increased non protein nitrogen content of the blood. It is better to have more than the minimum urinary output. With a good supply of water available from fluids drunk and food eaten the balance between intake and output will be maintained by the kidneys, the surplus water being used to facilitate the excretion of waste materials. On this basis a good water balance is shown by a good urinary output and a small volume of urine of high specific gravity, nearly always means there is insufficient water.

It is common knowledge that on the day of a major operation a low intake of fluid and food in most cases decreases the supply of water available. The exchange for the day is further interfered with by such abnormal fluid losses as blood, vomitus and the increased sweating induced by some anesthetics by the warm operating room and by the increased coverings of the postoperative ether bed. The total fluid thus lost may well exceed 3 liters and the output of urine for the operative day may be markedly diminished or absent. The practice of giving some fluid parenterally on the day of the operation particularly to the patient undergoing a long serious procedure is well founded.

Not infrequently the ingestion of fluid is interfered with for several days after operation or the disease alone may make it necessary for the surgeon to provide water. A knowledge of the daily water requirements of the surgical patient is then essential. With nothing taken by mouth the only water available without dehydrating the patient is that coming from the oxidation of body protein, fat and carbohydrate for energy. This usually yields less than 500 cc of water per day and for practical purposes this small amount can be disregarded. The surgeon should give sufficient water to provide for the daily excretions.

As in the healthy adult the excretion of water by the surgical patient is mainly for

two functions (1) the carrying away of waste materials through the kidneys and (2) the dissipation of body heat. Since the vaporizing process seems to have first claim on available water and since the kidneys function largely with what is left, the problem is to know what loss by vaporization amounts to and then give an additional amount of water for the kidneys.

An adult patient convalescing smoothly from a major operation vaporizes from 1000 to 1500 cc of water daily. With increases in heat production as from hyperthyroidism or fever from 1500 to 2500 cc may be vaporized daily even under comfortable environmental conditions. A safe estimate is 2 liters per day.

The amount of water for the urine is the next question. It has been stated that 500 cc of urine per day is the absolute minimum for a person with normal kidneys. Twice this amount, 1000 cc, enables the kidneys to carry out their function without having to work at maximum capacity and is a desirable volume for most surgical patients. For the patient with sepsis, 1500 cc of urine per day is recommended.

To summarize, the daily water requirements of surgical patients should be considered as follows:

Water for vaporization
Water for urine

*Uncomplicated
case*

1000-1500 cc.
1000 cc.
2000-2500 cc.

*Complicated
case (sepsis)*

2000 cc
1500 cc
3500 cc.

To these volumes required for normal exertions an additional amount because of an abnormal loss of fluid as by vomiting or drainage from an intestinal or biliary fistula, frequently must be added. If these losses are not taken into consideration, an apparently sufficient amount of water is actually insufficient, and a low urinary output of high specific gravity results. There are many causes of oliguria and anuria, but no other should be considered until the total water exchange including the abnormal losses for the few previous days has been checked over and dehydration as the etiologic factor has been eliminated. Generally, insufficient urine means insufficient water.

The patient who enters the hospital in a dehydrated condition presents another prob-

lem in water balance. An amount of fluid sufficient to provide for the daily exertions is not enough; an additional amount is necessary to make up for the fluid previously lost. Studies have shown that the common clinical signs of dehydration are present when a patient *deprived of water* has lost an amount of body water equal to 6 per cent of the body weight. This figure can be used in calculating the amount of water needed to overcome the dehydration factor in such a patient, example, for a 60 Kg patient, 6 per cent equals 3600 cc.

Dehydration in patients, however, is usually not a simple problem of water deprivation but is generally a combination of an inadequate water intake and a loss of electrolyte-containing fluid, as by vomiting. Because of the loss of electrolytes water alone will not correct the dehydration, but physiologic saline or Ringer's solution will since each of them has water and the chief electrolytes needed. The problem is how to give a sufficient amount of saline solution and yet avoid the dangers of an excess. In the sick surgical patient, which very commonly means a patient with sepsis or malnutrition or severe liver damage, or a combination of any of these, an excess of sodium chloride easily produces edema of the depen-

dent parts or even of the lungs and other viscera. The first thought of the surgeon on finding edema in a patient who has been receiving fluids parenterally should be, "What is the plasma protein level, and how much salt solution has been given?"

From a study devised to learn just how much salt solution to give to dehydrated surgical patients depleted of electrolytes, the following rule was developed. For each 100 mg that the plasma chloride level needs to be raised to reach the normal (560 mg per cent), the patient should be given 0.5 Gm of sodium chloride per kilogram of body weight.

This *clinical rule*, which was formerly advocated for the correction of dehydration and restoration of the depleted electrolytes

during the preoperative and postoperative periods has been shown to be dangerous and ineffective. It is dangerous since there are many individuals who are incapable of tolerating small quantities of salt in the immediate postoperative and postanesthetic periods. It is ineffective because the plasma chloride does not maintain a fixed relationship to the sodium ion and does not necessarily vary directly with the extracellular fluid volume. The restoration of the extracellular fluid deficiencies should not be made primarily upon the variation from the normal ions or molecules of the blood (carbon dioxide combining power, hemoglobin, plasma proteins, Cl, etc.) but upon the clinical status and physiologic response of the individual to the administration of parenteral fluids.

Programs for the maintenance of a normal water and electrolyte balance should be kept as simple as possible. The surgical staff should think of water requirements in terms of so much for vaporization and so much for urinary output. The administration of physiological saline or Ringer's solution for restoration of lost electrolytes to normal and their subsequent maintenance at normal levels can be carried out by volume for volume replacement. The subject of water and electrolyte balance forms an important chapter in preoperative and postoperative care and its skilful handling according to the needs of the patient will yield gratifying results.

POSTOPERATIVE CARE

General Postoperative Care.—While the general postoperative care is mainly carried out by the nurses, the surgeon is solely responsible for a smooth convalescence. The

comfort of the patient will depend on the intelligent and careful orders of the surgeon. The technical perfection with which an operation is performed is no positive index of the postoperative course. It is just as important to give the same meticulous attention to postoperative detail as to operative technique and there is no excuse for careless postoperative management. It has no place in surgery. The maintenance of fluid and electrolyte balance, thoughtful ordering of diet and sedatives and attention to the many other postoperative details must never be lost sight of by the careful conscientious surgeon. Attention to the details will often spare the patient many disagreeable complications and convert what might have been a stormy convalescence into an uneventful one.

Diet.—Most patients recover from an anesthetic either local or general naturally desire water. Vomiting invariably follows most surgical procedures. Therefore water is usually not permitted until from two to four hours has elapsed after the last signs of nausea have disappeared. Invariably water is given in teaspoonful doses moderately warm although occasionally the surgeons will order it ice cold. If the patient tolerates these small amounts well, greater quantities may be given but under an circumstances should a patient be permitted to drink freely and without restraint. If there are definite contraindications to the early oral administration of fluids, sucking cracked ice often relieves the agony of a dry mouth and an unquenchable thirst. It is not advisable to allow a fluid diet until the day following operation. The fluids commonly used are broths, gruel, plain tea and egg albumen water. Four ounces may be given at a time. An occasional patient may express a desire for ginger ale and very often this will be tolerated when all other liquids have failed. Orange juice and other fruit juices so frequently requested are not well borne by the majority of patients. Milk may be added on the second postoperative day. It is an almost perfect food for it is quickly digested and is almost entirely absorbed. Since it has a high caloric value it provides considerable nourishment. Unfortunately, however, some patients will not tolerate whole plain milk. Barley water, lime water

plain water seltzer Vichy or a little brandy added to milk will often overcome this intolerance. While as a general rule it is not a good policy to employ alcoholic beverages such as brandy or whiskey the writer believes that they have definite indications. Certainly a patient who has been accustomed to alcohol for years should be given it early in the postoperative course in sufficient amounts because sudden withdrawal might bring on delirium tremens. A person who is addicted to alcohol may require from 1 to 2 oz of whiskey three times a day. On the other hand some surgeons consider alcohol to be a definite and distinct stimulant prescribing it for weak and debilitated patients within the first days after operation.

Full fluids should be administered at frequent intervals and whenever possible they should be served warm. They should be immediately stopped if nausea or vomiting occurs. If the vomiting becomes pernicious or actual gastric dilatation is suspected a Levin gastric tube should be inserted and suction drainage applied without hesitation. Fluids may then be permitted freely if there is no postoperative contraindication. Naturally under these conditions whatever is ingested will be immediately siphoned but the psychic thirst of the patient will be relieved. The Levin tube may be removed as soon as the gastric fluid intake measures more than the output. It should be a routine nursing procedure in all institutions to chart the fluid intake and output as it is a rough method of estimating fluid balances. It is extremely important to know the quantity of fluid administered orally and parenterally, the amount of drainage through a Levin tube or an intestinal fistula and the amount of urine excreted. The urinary output will often give some clue to the activity of the renal function and will indicate beginning suppression and impending uremia, the early recognition of which is important.

A selected soft diet is usually allowed on the third day as a routine measure. This is permitted if the bowels have moved either naturally or aided by a cathartic or enema.

It must never be forgotten that the diet is a most important postoperative consideration. No two patients can be nourished alike for their individual calorie needs may be entirely different and it is a grave error

to feed patients in a routine manner. The factors which alter diet are many. The age, the general physical condition at the time of surgical intervention, the character of the operation and the postoperative course are important factors in determining not only the amount and kind of food but the frequency and manner of feedings. Many patients suffering from chronic diseases such as nephritis, diabetes, rheumatism and allied conditions will merit special consideration. A patient who has had an operation for hernia does not require the same type of food as one who has had a gastric or intestinal resection and the type of food given to a patient with enterostomy for ulcerative colitis will differ naturally from that given to a patient with a colostomy for carcinoma. A woman of sixty without teeth cannot be expected to digest the ordinary hospital fare with the same facility as a boy of twelve and a frail woman of 100 pounds cannot be expected to consume as much food as a laborer weighing 180 pounds.

Diets must be served under the supervision of an intelligent dietitian and the patient must be educated as to which foods are best for his condition. He should be warned against obliging relatives and kind friends who often bring home-cooked food and delicacies which may prove detrimental to his health. It is not unusual to have gastric disturbances occur after visiting days because of the candy and fruit which were surreptitiously smuggled in by visitors. This evil should be tactfully and carefully controlled. It has been stated with certain reservations that a soft diet provided the postoperative course has been smooth is allowed on the third day, and gradually other more solid articles are added until the so-called regular diet is tolerated. This is the usual routine following the simpler abdominal procedures such as appendectomy, cholecystectomy and the majority of gynecologic operations. Naturally if the peritoneal cavity has not been opened the patient may be given a soft diet on the second day. This is especially true following operations on the head and neck, orthopedic procedures and the majority of hernioplasties. There is no objection to it especially if the patient is hungry and expresses a desire for food.

There are exceptions to the usual routine of dieting especially in the field of intestinal surgery. Procedures involving the stomach duodenum and small intestine require unusual care. Fluids as a rule in these cases are not given until twenty-four hours after operation. The water and electrolytic balance in the meantime is maintained parenterally by Murphy drip or hypodermocentesis. Water is allowed in teaspoonful doses hourly starting the second day. If no untoward symptoms develop the amount is gradually increased as tolerated by the patient. Milk is then carefully added in measured amounts alternating with water and if this is well tolerated the patient may be safely started on the standardized Sippy diet. On the other hand a patient who has been subjected to colonic resection may have oral fluids much earlier usually on the first day but in these cases a low residue diet should never be given until sufficient time has elapsed to establish the competency of the intestinal suture line. Naturally in this type of case the administration of fluids by rectum is strictly forbidden.

Hypoproteinemia.—The importance of protein in surgical convalescence has recently been appreciated. Deficiency of body protein, or hypoproteinemia recognized by a lowered content of serum albumin and globulin of the blood may give rise to many postoperative symptoms. It may contribute indirectly to surgical shock, act as a factor in the suppression of urine and cause edema about a recent gastrointestinal anastomosis sufficient to produce obstruction. In some cases hypoproteinemia may give rise to peripheral edema and in others it may materially impair wound healing.

Treatment of hypoproteinemia consists in the replacement of proteins orally. Diets rich in amino acids such as milk cottage cheese lean meats liver eggs and soy beans should be prescribed. If this is impossible the intravenous administration of whole blood blood plasma and amino acids in the form of 5 per cent amigen and 5 per cent glucose will often effectively elevate the lowered protein content of the blood.

Sedatives.—Relief of pain after operation is of prime importance to the patients and the first duty of the surgeon is to prevent undue suffering. During the past decade

innumerable proprietary remedies have flooded the surgical literature but whatever may be said pro and con on their behalf morphine and codeine still remain the two absolutely dependable and reliable drugs. Their administration must be carefully controlled. They should not be given promiscuously since liberal and careless administration of these narcotics especially morphine has been responsible for drug addiction. It is customary to administer morphine hypodermically in $\frac{1}{4}$ gram doses with $\frac{1}{450}$ grain of atropine but here again judgment must be employed. The dose should be sufficient to control pain yet not large enough to cause toxic manifestations. Nurses universally have been duly instructed and warned of the depressing tendency of this drug and if the respirations become unduly slowed and other toxic symptoms are manifest no time should be lost in administering the appropriate antidote. In those cases in which morphine produces nausea or stimulation or in which there is sensitivity to it, atropine or dilaudid may be used hypodermically. It is a good plan to substitute codeine for morphine as soon as possible and as conditions improve to make another change employing one of the invaluable barbiturate derivatives. For restlessness without marked pain triple bromides phenobarbital (luminal) nembutal or secobarbital should be employed. A highly neurotic patient who persistently begs for hypodermic medication will often be relieved of the most terrific pain by a sterile hypodermic injection of saline solution.

Occasionally toxic psychosis develops after operation and the patient becomes irrational and difficult to control. Hyoscine hydrobromide by hypodermic injection or paraldehyde chloral or avertin by rectum in sufficient doses will usually control the maniacal manifestations of these unfortunate persons and will tide them over until consciousness or orientation has been established.

Pneumonia.—Pneumonia still remains one of the most serious postoperative complications. It still augments surgical mortality and morbidity in spite of the use of sulfonamides and oxygen therapy. A full discussion of postoperative pneumonia has been given elsewhere but it is so important that it may

not be amiss to repeat and emphasize a few points. Pulmonary complications are more frequent in the aged because they are especially prone to hypostatic congestion. Pneumonia is more apt to follow operations involving the upper abdomen because of subsequent reflex diaphragmatic paralysis leading to lateral pulmonary atelectasis. There is much which can be done to combat these factors prophylactically. Frequent careful changes of the position of the patient in bed will do much to diminish the incidence of pulmonary hypostasis. Careful administration of carbon dioxide gas will stimulate and increase the depth of respirations by hyperventilation of the lungs. At no time should the respiration be hampered. Great care should always be taken that free respiratory movement is not hampered by cumbersome and confining dressings. Adhesive plaster if used for upper abdominal wounds should never be applied across the abdomen in such a way as to restrict the respiratory movement of the lower ribs completely. These simple instructions if religiously followed will do much to diminish the frequency of postoperative pneumonia.

Pulmonary Atelectasis.—In those cases in which a diagnosis of pulmonary atelectasis has been made if a cough, a change of position or a slap on the back does not discharge the mucous plug bronchoscopy expertly performed may be extremely efficacious in removing the bronchial secretion by suction.

Out of Bed.—The patient may be permitted to leave his bed when the surgeon feels that the patient's general and local condition will permit the additional strain. A patient with a clean non-drained abdominal wound is permitted to sit up in bed in from five to twelve days and allowed up in a wheel chair in from ten to fourteen days. There are those of the radical school who encourage the patient to get up as soon as the sutures are removed while those of the conservative school will not allow a patient up until after from sixteen to twenty-one days. A prolonged stay in bed is advised in those conditions in which healing is apt to be delayed especially in cases of carcinoma and recurrent inguinal hernia and the ordinary cases of postoperative ventral and primary umbilical hernia. In the final analysis there

can be no set rule each case must be judged on its individual merits. After the patient has been about in a wheel chair and has developed sufficient strength walking may be permitted. This should always be done under guidance and the patient should never be permitted to indulge to the point of fatigue. [There is now considerable evidence that early ambulation not only is very beneficial to the patient as a whole but is harmless to the wound itself. Particularly in cases in which a transverse abdominal incision has been used the patient is allowed out of bed for a short time on the second or third postoperative day and walking is increased each day thereafter.—Ed.]

Treatment of a Postoperative Wound.—**Clean Wound.**—Tissues if handled gently at operation under ideal sterile conditions with careful hemostasis and accurate approximation should heal by primary union. The simplest treatment of a non-drained abdominal wound is best. If the postoperative course is normal an abdominal wound may be dressed on the seventh day if the temperature is elevated or the general condition of the patient is not satisfactory the wound must always be inspected without hesitation. Skin sutures of various kinds are removed on the seventh day and deep retention sutures if employed removed on the tenth to the fourteenth day. Michel or other similar types of metal clips because of the fact that they are apt to cut into the skin and leave disfiguring pockmarks should be removed on the fifth or sixth day after an abdominal operation and on the second day after an operation on the thyroid. If after removal of the sutures a skin wound appears to be poorly healed even if the edges are firmly approximated no harm can accrue from further supporting the wound with sterile adhesive straps.

Hematoma.—Hematoma is not an infrequent complication of a postoperative abdominal wound. As a rule it is a reflection on the operative hemostasis. While a hematoma in itself is not serious if infection occurs serious complications may develop. The treatment depends mainly on its size. If it is small absorption may take place under conservative treatment. If large it may liquefy and subsequently be evacuated either by aspiration without any further measures or the

wound may be incised in its most fluctuating areas and the blood clot evacuated. Occasionally an operative ligature may slip and from the spread of the ecchymosis it may be evident that active bleeding is taking place. In these cases the patient should be immediately taken to the operating room where under ideal surroundings the wound may be reopened, the blood clot evacuated and the bleeding vessel caught and ligated.

Infected Wound.—If inspection of the wound reveals an inflammatory reaction the proper treatment should be immediately instituted. If cellulitis is present all effort should be made to localize the infection. Dry or moist heat, poultices and other counter irritants have all been found most efficacious. Once the infection has localized the wound should be opened and adequately drained for when frank suppuration is present ventilation is required and the radical drainage of a wound is the most conservative measure in the treatment of infections of this order. An infected wound regardless of its location drains better with wet than with dry dressings. It appears to be of little moment what solution is used to moisten the dressings but they must be kept wet not simply damp. Dressings may be kept moistened either by frequently changing them or by covering the wet gauze with rubber tissue which prevents evaporation or by inserting a rubber catheter in the dressings and introducing fluid through it at stated intervals.

Gas Bacillus Infections.—(See section on Gas Gangrene.)

Drained Abdominal Wound.—Treatment of drained abdominal wounds varies according to the routine of the individual surgeon. A few general rules however may be enumerated. Drainage tubes drains and packing should not be removed either too early or completely at a single dressing. Drains should be progressively shortened as the discharge diminishes. Then the facts should be recorded on the patient's chart. If a fecal fistula develops the drainage material should be removed immediately because its presence might serve only to compromise further the damaged intestinal wall.

If the discharge from a deep abdominal wound is fecal or is extremely purulent and copious it is advisable to irrigate the wound

gently through one of the drainage tubes with some warm solution. This may be repeated as often as necessary. Irrigation should always be carried out gently, the pressure of the fluid should always be low and only a small amount should ever be introduced.

Fistula.—It is most important to protect the skin about any draining wound carefully, especially if it shows the slightest tendency to become irritated by the discharge. This is especially true in those cases in which a gastric, duodenal or intestinal fistula has developed. The skin may often become irritated following cholecystectomy, especially if there is a biliary fistula and particularly if the bile contains activated pancreatic ferments. The most important prophylactic measure in these cases is to keep the drainage from coming in contact with the skin. This may be accomplished by continuous electrical or water pump suction which will keep the wound practically dry. If this apparatus is not available the wound should be left exposed and watched constantly by a nurse. As soon as any drainage appears in the wound area it should be gently sponged away with cotton wipes.

Another distinct advantage of suction is that gastric, biliary and duodenal secretions that are of value to the patient may be collected and saved. If necessary the drainage may be re-fed to the patient through a Levin gastric tube or through a jejunostomy tube.

The skin itself may be protected against the irritating digestive ravages of some of these secretions by a variety of substances. Lanolin, paraffin, Beck's paste and bronze powder are invaluable. Wet dressings soaked in beef juice, especially in cases of gastric and duodenal fistulas have proved to be efficacious in controlling the digestive action of the various ferments.

Disruption of an Abdominal Wound.—Disruption of an abdominal wound or dehiscence with or without exposure of the abdominal contents (evisceration) is a rather rare complication occurring in from 1 to 2 per cent of all abdominal cases. It is important to be familiar with the condition and recognize its implications because it is an extremely difficult postoperative complication and is attended by a high mortality. It is most apt to occur in illnesses of a pro-

tracted nature attended by emaciation and anorexia and weakness and in those cases of acute and chronic intoxication associated with long periods of fever. These conditions devitalize the patient sufficiently to interfere with the reparative powers of the tissues and with healing of the wound. Therefore it is a likely complication in carcinoma and is not infrequently seen in certain gynecologic conditions especially those of a malignant nature and in uterine fibroids. The diagnosis is simple and rarely offers difficulties. A dressing previously dry and clean which suddenly becomes stained a salmon color or saturated with a bloody serous discharge should make one exceedingly suspicious of dehiscence even if inspection shows that the skin is apparently healed. If palpation however gives the impression that the underlying tissues have separated the removal of one or two skin sutures will readily confirm or allay the suspicion.

Occasionally in a case of dehiscence the patient may present the early symptoms of acute intestinal obstruction due to subcutaneous kinking of a prolapsed knuckle of intestine. Quite often an intelligent patient can make his own diagnosis by being conscious of a sudden 'giving away' of the operative wound following some excessive strain. The diagnosis calls for immediate active surgical intervention. There are several methods of treatment available. The most important however is either the tampon method or secondary suture of the abdominal wall with drainage. The tampon method is the simplest easiest and least shocking. It should be the method of choice when infection is present or in the case of a desperately ill patient in whom disruption occurs secondary to general peritonitis.

The treatment consists in thoroughly washing the prolapsed omentum and intestines with copious saline irrigations and then gently replacing the exposed viscera within the abdomen keeping them in place with iodoform gauze packings. The edges of the wound are then approximated with sterile adhesive straps. This procedure can be carried out with the patient in bed and without an anesthetic. The packing is gradually removed as healing progresses. Secondary su-

ture with interrupted heavy through and through silk sutures is more complicated and it necessitates the use of an operating room and anesthesia. Such a wound is always drained and as a rule six weeks must intervene before the patient can be discharged.

RALPH COLP

POSTOPERATIVE COMPLICATIONS

Abdominal Distention.—Postoperative abdominal distention is a condition arising primarily on the basis of muscular atony of the gastrointestinal tract in which gas collects within the lumen of the gut, this in turn causes a localized or generalized increase in the girth of the abdomen displacement of organs stretching of tissues including any abdominal incisions that have been made and sensations of tenseness and discomfort if the digestive tract is quiescent cramping colicky pains if intestinal movements are active. Distention occurs so regularly after laparotomy, especially after operations on the upper abdominal organs that it may be regarded as the usual consequence of these operations. It varies in degree from slight flatulence to the extreme degree seen in toxic shock. The physical findings consist of generalized or localized increase in the size of the abdomen together with increased tympany on percussion plus abnormal findings on auscultation disordered peristalsis with borborygmi in case intestinal movements are active and a silent abdomen in cases of paralyzed musculature.

Mere surgical exposure of the contents of the abdomen to air usually produces prompt cessation of all intestinal movements. Under splanchnic or spinal analgesia however considerable activity may persist for variable periods. The customary interpretation of these facts is that the muscular atony induced by laparotomy is essentially a reflex phenomenon mediated by the splanchnic or inhibitor innervation. The primary atony can presumably be exaggerated and prolonged by such general conditions as psychic apprehension and dehydration which affect the sympathetic nervous system and more especially by local peritoneal reflexes instigated by damage to the peritoneum such as result from ordinary handling retraction

mechanical pressure by gauze packs or drainage material or the irritation of inflammatory exudates whether resulting from bacterial action or not. It seems likely that disturbances of secretory and absorptive function go hand in hand with disturbances of motor activity and resumption of function occurs first in a disorderly fashion.

For a variable period of time postoperatively usually for from twelve to twenty-four hours the intestinal tract is in a quiet state, during this period distention may be slight or considerable but the patient usually suffers little. With the resumption of motor function however the character of the distress changes and definite cramping colicky pains are experienced the so-called gas pains.

As the normally functioning intestine finds greater difficulty in propelling and expelling gas than semisolid and solid contents it is not surprising that a bowel which is functioning in a subnormal and disorderly fashion is largely powerless to deal with gas. Furthermore whereas the gaseous contents of the normal bowel consist largely of carbon dioxide which is formed by processes of putrefaction or the action of digestive ferments and which is easily absorbed by the blood stream and excreted through the lungs the gas of postoperative distention is largely atmosphere air four fifths of which consists of nitrogen a gas which is absorbed only very slowly (McLver *et al*).

Treatment.—On the basis of the preceding discussion of the etiology it will be appreciated that the treatment of postoperative distention is preeminently prophylactic. All those factors which tend to disturb the motor and secretory functions of the bowel should be reduced to a minimum—preoperative purgation and catharsis starvation with respect to both food and water operative exposure to the air drying chilling and manipulation of the intestine, air swallowing should be prevented as far as possible by skill in inducing and maintaining general anesthesia and combating postoperative retching gagging and vomiting. From the point of view of this particular complication spinal and spinal anesthesia offer a distinct advantage over general anesthesia in that they both tend to stimulate rather than to depress peristalsis.

On the theory that the normal mechanism for disposing of the gas of abdominal distention is absorption not expulsion some authorities advocate only conservative therapy. This includes provision for escape of any gas spontaneously finding its way to either end of the digestive tract relief of external pressure on the abdomen and spasm of the abdominal wall and liberality in the exhibition of narcotics (morphine) for the relief of acute discomfort.

A Levin catheter passed through a nostril into the stomach and left there provides a means for decompression of the proximal end of the digestive tract. Once gas has been evacuated from the stomach how far it is likely that some gas in the duodenum now finding a favorable pressure differential will regurgitate into the stomach and escape through the tube. Ultimately the expectation is to hope that some degree of decompression of the entire small intestine may occur in this way. From this point of view it would seem desirable to pass the catheter directly through the stomach into the duodenum if possible. Application of Wangensteen's suction to the free end of the catheter obviously creates a still more favorable condition for the evacuation of gas by providing gentle negative pressure. In cases in which Wangensteen's suction is not effective introduction of a Miller Abbott tube may be tried remembering however that the two conditions for its successful use are not as likely to be present as in dynamic ileus *viz.* that it can be made to pass the pylorus in the first instance and in the second instance that once it has found its way into the duodenum peristalsis will be sufficiently active to carry it down the intestine. Free means of escape for any gas finding its way into the rectum is provided by insertion of a soft rubber rectal tube. Such a tube may be introduced for an hour at a time at intervals of an hour or more.

The unavoidable distention caused by gas which can find its way in neither direction can be relieved by loosening whenever possible tight mechanical bandages and other appliances elevation of the bedclothing on a suitable wire cage or cradle to relieve local pressure on the abdomen and the application of heat to relieve muscle spasm (though recent experimental evidence suggests that

intestinal activity may be inhibited by application of heat to the abdominal wall—Bisgard and Nye) dry heat in the form of irradiation from incandescent electric globes has the advantage over moist heat that it can be made to affect the whole expanse of the abdomen even that portion covered by bandages and also that it can be kept optimally constant without periodically disturbing the patient or moistening the bed clothes.

Those who think that peristalsis must be largely relied upon for the evacuation of gas advocate the use of stimulating drugs and perhaps also enemas and flushes. The time-honored enema and flush whether plain or medicated with soapuds turpentine or eall peppermint or other substances is at present widely regarded as of questionable value largely because it may increase rather than relieve discomfort particularly if carelessly administered. The status of drug therapy in the treatment of intestinal atony in general and distention in particular is highly controversial. Opiates, physostigmine, prostigmine and the derivatives of choline have been found experimentally to stimulate motility of the small intestine and pitressin (one of the active principles of pituitrin) to stimulate motility of the large intestine. Some authorities however find that the small intestine and colon obey a law of reciprocal activity such that when one is active the other is inactive. Thus all of these drugs may have opposing actions which tend to cancel each other out. The synthetic substance prostigmine seems to be the best single drug for stimulating peristalsis according to clinical experience but a combination of drugs may be more rational (ergotamine tartrate 0.25 mg., prostigmine methyl sulfate 0.25 mg., and pituitrin 125 units as advocated by Adler, Atkinson and Ivy). Intravenous injection of hypertonic sodium chloride solution causes strong peristaltic activity in experimental animals and has been advocated for clinical use (20 cc. of a 10 per cent solution introduced very slowly—four to five minutes is recommended by Orr).

No patient with abdominal distention should be treated without constantly bearing in mind the fact that the distention may be transient and almost physiologic or it

may be an indication of incipient peritonitis, mesenteric thrombosis or intestinal obstruction.

Dilatation of the Stomach.—Dilatation of the stomach differs from simple distention in several important particulars. The contents of the distended stomach are mainly gaseous whereas the contents of the dilated stomach are mainly fluid, the fluid contents of the latter are very obviously products of secretion because reaccumulation of the fluid occurs rapidly and repeatedly after complete evacuation of the stomach by intubation even though nothing is taken by mouth in the interim. Distention of the stomach produces discomfort which borders on pain whereas dilatation may produce little discomfort and few symptoms except regurgitation. Distention of the stomach tends to undergo spontaneous recovery, dilatation tends to progress rapidly to a fatal termination.

Dilatation of the stomach may occur both early in the postoperative period and abruptly death on the operating table has been reported as due to this condition.

Acute dilatation of the stomach is probably due to reflex gastric inhibition either visceral or sensory nerves forming the afferent limbs of the reflex arc and the splanchnic and vagus nerves forming the efferent limb. Distention of the organ is then superimposed in the first instance by swallowed air and later by accumulation of normally secreted gastric juice and regurgitated duodenal secretion, pancreatic juice and bile. Inasmuch as these secretions cannot be appreciably absorbed from the stomach or duodenum they accumulate passively and the natural progress of the condition is fatal especially because of failure to absorb chlor-

effortless regurgitations then recur at short intervals and soon the originally watery material becomes streaked with green or black. If the patient is conscious he characteristically complains of some gastric distress at this stage and inspection of the epigastrium may reveal definite localized fullness. Later if nothing is done to relieve the condition regurgitation of large quantities of brownish or greenish fluid occurs. As more and more fluid is evacuated dehydration and hypochloremia develop, the eyes become sunken, the tongue becomes coated and dry and the face looks drawn and anxious.

Treatment—Dilatation of the stomach does not occur in rationally and skilfully treated patients except in rare instances. Immediately after all laparotomies involving manipulations above the level of the umbilicus prudence dictates gentle gastric lavage and in most cases the nasal catheter used for this purpose should be left in situ in order that aspiration may be subsequently performed at suitable intervals. Aspiration of gastric contents should be performed with out hesitation for all other patients who for any reason do not appear to be doing well or who vomit more than once. The cause of the condition would not always be relieved thus; it is true but acute dilatation of an empty stomach obviously cannot occur and in most cases of acute dilatation the condition begins as it probably does without organic obstruction and becoming progressively worse and more complete only as the viscus becomes increasingly distended would be completely obviated.

Established gastric dilatation amounts to a special instance of high intestinal obstruction and the treatment is that of high intestinal obstruction—functional in type unless there is some particular reason for assuming the presence of an organic stricture. Accordingly the indications are for decompression of the stomach in order to avoid mechanical distortion of the gastrointestinal tract and equilibration of all factors concerned with establishing and maintaining motility of the gastrointestinal musculature especially the water balance and ionic balance.

In many cases the device described by Wangenstein in the section on intestinal obstruction is preferable to simple periodic suction not only because it removes gastric

secretion and gas as fast as they accumulate thus keeping the stomach (and most likely the duodenum and at least part of the jejunum as well) quite empty but also because with such an apparatus functioning properly the patient may be allowed to drink freely the fluid drunk being of course promptly aspirated from the stomach by the apparatus. Drinking copiously even though the fluid does not remain in the stomach provides a means of keeping the mouth and throat moist and to some degree combats thirst which may be greatly annoying. When Wangenstein suction is used accurate charting of fluid given by mouth and fluid and gas evacuated from the stomach must be performed both for the purpose of ascertaining whether the apparatus is working properly and also to detect the first signs that fluid is starting on its way down the intestinal tract which may be regarded as a signal of recovery. When Wangenstein suction is continued for considerable periods of time (it may be employed for days if necessary) two dangers must be recognized: (1) production of alkalosis resulting from prolonged removal of chlorides from the stomach and (2) pressure damage to the esophagus or larynx. Alkalosis may be prevented by parenteral administration of salt solution. The use of Miller Abbott double-barrelled tubes which provide a means of withdrawing gastrointestinal contents at one level while at the same time adding nutritionally prepared solutions at another level would theoretically be ideal (decompression of the stomach; addition of water, essential ions and even food to the small intestine) but the practical difficulties are similar to those mentioned under the treatment of abdominal distention.

Disturbances of Urination—*Suppression, Anuria, Oliguria and Retention*—By far the most frequent cause of anxiety with respect to the urinary tract in postoperative cases is failure of the patient to void. Postoperative failure to void may be due to (1) acute failure of the urinary function in the kidney itself, suppression or secretory anuria; (2) blockage of the ureter, anuria or postrenal anuria; and (3) failure of the bladder to empty itself of contained urine, retention. All the conditions are more likely to be partial than complete and accordingly

to cause oliguria rather than complete failure to void

Excretory or secretory failure of the kidney itself suppression of urine according to some observers is sometimes due to reflex or idiopathic causes but probably in the majority of cases is due to more definite factors such as low blood pressure dehydration and blood concentration Fundamentally therefore the treatment is prophylactic and consists in adequate preoperative study of the patient to detect abnormalities of structure and function plus preservation as closely as possible of a normal condition of hydration Curatively the slow intravenous injection of considerable quantities of isotonic or in the more severe cases hypertonic solutions of dextrose may rather promptly reestablish the urinary function Ureteral catheterization is occasionally said to accomplish the same result

Postrenal anuria may be due to any one of a number of conditions capable of producing occlusion of the ureter periureteral edema extraurethral tumors inadvertent sectioning or ligation of the ureter and impaction of a preexisting renal calculus calculous anuria The greatest number of cases follow operations on the uterus and broad ligaments in which case the condition is most often due to edema and is accordingly transitory Complete and permanent blockage of a ureter as by ligation or occlusion by a calculus is rare and necessarily results fatally only in those cases in which the only adequately functioning kidney is on the side of the occlusion

In view of the widespread use of sulfonamides in connection with operations it is important to realize that these substances may form crystals and calculous concretions of crystals in the urine which are capable of producing anuria Because these substances especially sulfadiazine sulfathiazole and sulfapyridine may be several hundred times as soluble in alkaline urine as in acid urine alkalinization with sodium carbonate or sodium citrate by mouth or some equivalent substance by vein (lactates) constitutes an important prophylactic measure against this kind of anuria

Postoperative retention of urine may be due to failure of the urinary bladder to contract with sufficient force to empty itself

True retention of urine can be said to occur only when the bladder has become abnormally full of urine and the practice of referring to every case of postoperative failure to void as a case of retention is pernicious in that it entirely avoids this issue obviously a bladder may fail to empty itself simply because it contains very little urine or none at all Furthermore and just as important patients with retention may actually dribble urine at frequent intervals and still maintain an overdistended bladder this condition is known as distention with overflow Retention frequently follows operations on the urethra itself or adjacent structures and in such cases is due to such factors as impaction of blood clots periurethral edema or too tight vaginal or rectal packing certain operations such as prostatectomy in the male and repair of a cystocele in the female in variably require the use of an indwelling catheter for some days postoperatively to obviate the effects of these mechanical factors When the cause of retention is not discoverable it is most frequently ascribed to atony of the bladder

Within limitations there is much difference of opinion as to the necessity of and indications for postoperative catheterization Most observers agree that the normal urinary bladder is not easily infected as a result of instrumentation Evidence in support of this theory is seen in the relative infrequency with which cystitis develops after properly performed cystoscopy When cystitis develops after catheterization there fore even after repeated catheterization the presumption is either that the bladder was already the seat of an unrecognized abnormality or was damaged as by long-continued overdistention or that the technic was faulty with respect to asepsis On the one hand are those who contend that the mere passage of some definite interval of time such as ten or twelve hours without voiding constitutes sufficient indication for this procedure on the other hand there are those who rarely or never catheterize a patient preferring to allow the accumulation of urine to force the sphincter regardless of the time interval the volume of the urine and even the discomfort of the patient Between these two extremes are others who catheterize or do not catheterize according to specific indications

Probably the safest procedure is to etherize if distention is causing discomfort if the patient passes small quantities of urine at frequent intervals (which would suggest the presence of retention with overflow) or if inspection or palpation of the suprapubic region reveals a distended viscus the objection to allowing the bladder to become distended by the accumulation of more than 300 or 400 cc. of urine is that the organ may suffer mechanical damage especially in the case of the middle aged or elderly patient whose tissues have lost some of their natural elasticity. Catheterization is employed ordinarily only after all reasonable attempts have been made to stimulate spontaneous voiding such as by changing the position of the patient in bed or if at all feasible even allowing a suitably supported standing or squatting position. It should be remembered that some patients find it impossible to void while an attendant is in the room.

In all cases in which catheterization is required and in all cases in which there is a suspicion that the urinary tract has been the seat of a recent infection there should be repeated microscopic examinations of the Gram stained sediment for bacteria. The microscopic diagnosis of urinary infection can precede the development of clinical symptoms and signs by many hours. One of the sulfonamides preferably sulfadiazine in doses of 0.5 Gm. three times per day may be given prophylactically in cases requiring an indwelling catheter or in other cases in which there is special reason to anticipate infection.

Postoperative Pulmonary Complications—That surgical procedures do not usually predispose to the development of pulmonary lesions is shown by the fact that in from 2 to 6 per cent of all patients subjected to major surgical intervention pulmonary lesions develop whereas for some types of operations the incidence is 10 to 13 per cent (47 per cent in males following operations on the stomach and duodenum 36 per cent after operations on the gallbladder—Betts). To account for this predisposition several theories have been proposed all of which have as their basis controlled clinical observations and experimental evidence.

The Aspiration Theory—This is the most natural theory as it assumes that aspiration

of such substances as saliva mucus and vomitus together with such pathogenic micro organisms as are invariably present in these substances is mainly responsible. Formerly considerable emphasis was placed on the abolition of the cough reflex during general anesthesia and of the swallowing reflex during tonsillectomy and related operations under local anesthesia as etiological factors and indeed it has been rather conclusively shown that some aspiration of material from the mouth and throat into the trachea and bronchi invariably occurs under these conditions unless a definite Trendelenburg position is adopted and maintained (Lemon). One fact however of universal acceptance seems to cast serious doubt on the supreme importance of aspiration as an etiological factor viz. that pulmonary complications develop with equal or almost uniminished frequency after splanchnic spinal and other anesthetics which do not disturb the swallowing and cough reflexes at all and are therefore presumably not associated with aspiration.

The Embolic Theory—According to the embolic theory major emboli or showers of minor emboli originating from the upper respiratory tract from thrombotic veins in the environs of operative areas elsewhere in the body from some intracutaneous thrombus at a distance from the operative site or even from a coalescence of the normally emulsified fat of the blood stream (Laliman *et al.*) are carried to the lungs where they set up vascular occlusive or frankly infectious processes depending on circumstances. Major pulmonary embolism and infarcts are of course universally conceded to occur in this manner.

The Atelectatic Theory—According to this theory, pulmonary complications are due to collapse of a greater or lesser volume of pulmonary tissue. A plug of viscid mucoid secretion is inspired into the bronchial tree at some point and blocks both ingress and egress of air absorption of residual air then occurs from that portion of the lung distal to the point of impaction and because this tissue becomes functionless and its circulation is profoundly disturbed it readily becomes infected.

Postoperative pulmonary complications occur at least twice as frequently in men as

in women. They are rare following operations on the head, neck and extremities (approximately 0.5 per cent) more common after lower abdominal operations and herniorrhaphies (about 1 per cent) but surprisingly common after operations on the upper abdominal organs: stomach, biliary tract, pancreas and spleen (10 to 13 per cent or more). Pre-existing or incubational respiratory infections act as a definitely predisposing factor: smears and cultures from infectious postoperative lesions of the lungs and bronchi invariably reveal those organisms which characteristically have their habitat in the mouth and pharynx and about the teeth (Smith).

Academically postoperative pulmonary complications can be classified as (1) mechanical (atelectasis and massive collapse), (2) vascular (infarction and embolism) and (3) infectious (abscess and pneumonia). Clinically the most serviceable classification is simply early and late. The early complications alone are discussed in this section and as a matter of fact only the obscure part of this group: Frank pneumonia, massive collapse of the lung, infarction, embolism and gangrene have been given their appropriate consideration elsewhere.

The obscure group of early pulmonary complications usually show their characteristic symptoms and signs within the first two or three days postoperatively, run their course within about five days though physical signs may persist for as long as two weeks, subside spontaneously and rarely show complications or sequelae. The symptoms consist of elevation of the temperature to 101° to 105° F. without chill, rapid shallow breathing, the upper portion of the thorax alone showing much excursion, a rapid weak pulse, cough (at first unproductive and not associated with physical signs later productive of purulent but not blood-tinged phlegm in considerable amounts) and scattered coarse rales. Formerly patients with such symptoms were given the diagnosis aspiration pneumonia, either pneumonia or surgical pneumonia. Lately terms are commonly used which imply a different etiology: mild or evanescent atelectasis (Mastics), partial atelectasis or hypoventilation (Muller). The group of entities embraced by these various names

though obscure probably accounts for by far the greatest percentage of all pulmonary complications. At the base of the lungs certain early postoperative changes of a definite nature can frequently be demonstrated by roentgenographic examination or even by very careful physical examination which are not associated with any definite clinical symptoms which are usually transitory, which resolve spontaneously and which usually go unrecognized. The skiagram reveals diffuse cloudiness and some mottling and the physical signs consist of diminished percussion sounds, altered breath sounds, rales and tubular breathing. These changes are believed to be due to purely physical factors such as a diminished respiratory excursion due to partial fixation of the lower portion of the lower thorax and relative fixation of the diaphragm, pressure phenomena due to recumbency in bed and possibly also areas of minor atelectasis dependent on bronchial occlusion. It is widely believed that this is the initial process from which by the superimposition of infection most of the other and more severe processes develop.

Pneumonia—(See section on Pneumonia.)

Embolism—(See section on Embolism.)

Massive Collapse of the Lung—(See section on Atelectasis.)

The prophylactic treatment of postoperative pulmonary complications is of fundamental importance. It should be remembered that pulmonary complications are especially likely to develop in men, particularly those who have undergone a surgical operation on the upper abdominal organs. Because such complications tend to occur with especial frequency during epidemics of common colds, influenza, tonsillitis and infections of the upper respiratory tract generally, it should be axiomatic to postpone operations of election on patients who have recently contracted or have been exposed to infections of the respiratory tract and to suspend all but emergency operations during epidemics of such infections. For a similar reason preliminary elimination of all known foci of infection in the mouth and pharynx should precede major operations whenever sufficient time can be allowed for interval healing of the tissues. During the period of anesthesia great care should be taken to prevent general chilling of the patients.

body exposure to drafts and aspiration of saliva mucus and vomitus. Operating with the use of spinal or other forms of local or regional analgesia probably offers no protection or certainly very little.

Those who adhere to the atelectatic theory of development of most of these complications stress the importance of enforcing normal or exaggerated breathing as far as possible thus maintaining expansion of all parts of the lungs. Administration of a suitable mixture of carbon dioxide and oxygen with a gas anesthesia machine for several minutes before the patient leaves the operating table regardless of the form of anesthesia is widely advocated. After return to bed breathing into and out of an ordinary paper bag for five minute periods several times per day is a convenient method for continuing CO_2 hyperventilation in case the patient can and will cooperate. (For technic see the treatment of hicough in the next section.) Deep breathing exercises under the supervision of the nursing staff at stated and frequent intervals during the first few postoperative days are commonly advocated. Some authorities however condemn such procedure as actually favoring the aspiration of plugs of secretion. All seem agreed however that frequent changes of the patient's position in bed are valuable. To be of real value the change of position should if possible be a deliberately planned careful turning of the patient from the dorsal recumbent position to the side or back again as the case may be at intervals of two hours or so. Because experiments show that up to 59 per cent depression in vital capacity may be caused by reflex inhibition of respiration due to pain caused by upper abdominal incisions blocking of the fifth to eleventh intercostal nerves has been advocated by Zollinger to favor deeper respiration in these cases.

When postoperative pulmonary complications definitely develop careful nursing care and the administration of oxygen either alone or in combination with carbon dioxide placing the patient in a sitting or semi sitting position symptomatic and supportive measures and attention to the emunctories and water balance constitute the important part of the treatment. In view of the difficulty of differentiating in the case of an acutely ill patient between early lobar or lobular pneu-

monia which are responsive to sulfonamides (and penicillin) and atelectatic lesions which presumably are not responsive careful attention may well be given to the possible usefulness of early specific therapy with these drugs.

In certain cases special forms of treatment are occasionally indicated. Thus in accordance with increasing appreciation of the role of atelectasis in the production of these lesions early introduction of a bronchoscope should be considered as a possible means of discovering and relieving any bronchial obstruction which may be present provided someone thoroughly skilled in the use of the bronchoscope is available.

Postoperative Parotitis—Postoperative parotitis is the non specific infection of the parotid gland with microorganisms of the pyogenic group. Although the parotitis may resolve spontaneously and completely it shows a remarkable tendency to progress to frank abscess formation or gangrene. It is an affection of middle aged or older adults rather than younger persons it afflicts females more frequently than males and develops in somewhat less than 10 per cent of all patients subjected to major surgical procedures. This complication tends to occur in patients debilitated by long illness prior to operation or in those whose postoperative convalescence is delayed and stormy.

Staphylococci seem to be the causative organism in most cases but pneumococci streptococci and even *B. coli* are often recoverable from an infected gland. The mode of establishment of the infection is not certain some cases may be due to metastatic blood borne infection and others to lymphatic extension but it seems reasonable to believe that most cases represent mechanical extension from the mouth by way of Stensen's duct. The trauma of the anaesthetist's fingers exerting undue pressure at the angle of the jaw may act as a predisposing factor though the complication is seen in patients operated on under spinal and local analgesia. Failure of the normal mechanical sucking action of saliva from the gland secondary to dehydration or failure to chew resulting in stagnation of secretion in the duct system and dryness of the mouth is probably an important factor.

The essential symptomatology consists of

painful localized swelling at the angle of the jaw together with the usual indications of systemic intoxication—fever, increased pulse rate and leukocytosis. In some cases the symptoms are all slight, the temperature being elevated only a degree or two and the tumefaction being strictly localized in fulminant cases, however, the temperature may be elevated to 104° or 105° F. and the patient may show spreading edema of the neck face and head accompanied by other evidences of profound sepsis.

The important considerations in the prevention of postoperative parotitis are careful attention to oral hygiene, prevention of dehydration, preservation of the function of chewing—as by having the patient chew gum—and avoidance of trauma to the parotid gland during the induction and maintenance of general anesthesia.

When the condition actually develops an attempt should first be made to demonstrate and insure patency of Stensen's duct; if there seems to be a possibility of impaction of a calculus or inflammatory stenosis. Otherwise except in the fulminant cases the treatment may be conservative and supportive for a period not to exceed forty-eight hours, an attempt being made during this interval to favor spontaneous resolution without pus formation by the application of heat in the form of hot moist compresses over the involved area. Advantage should be taken of the probable usefulness of sufficiently large doses of sulfonamides or penicillin which should be given early. At the Mayo Clinic (Rankin and Palmer) radium application over the affected gland has proved to be of definite value particularly if the application is made within one or two hours of the recognition of the complication. From two to four 50 mg. tubes of radium are applied at distances of 2.5 cm. from each other, filtration being provided by 2 mm. of lead, 1 mm. of brass and 0.5 mm. of silver and a dosage of from 800 to 6000 milligram hours is given depending on the estimated extent of the process. Many who have used this form of therapy regard it as virtually specific. There seems to be no reason why roentgen treatment should be less efficient than radium treatment if the latter is not available and the patient can be safely moved to a suitable x-ray machine or if the machine can be

transported to the bedside. An estimated suitable application in the latter case is 40 to 50 per cent of one erythema dose filtered through 4 to 6 mm. of aluminum at a moderate (135) kilovoltage (Decker).

In the early fulminant cases and in the milder cases which become more serious with the passage of hours, radical incision and drainage should be practiced without hesitation for the gland has a firm capsule and is deeply placed, thus making it practically impossible to determine whether suppuration has or has not actually occurred, extensive suppuration or even gangrene may otherwise develop undetected.

The mortality in postoperative parotitis may in any considerable series of cases approach 40 per cent, though this mortality is by no means solely due to the complication itself; the general condition of the patient usually being poor. If radium is applied early and drainage is instituted on slight indications the mortality may be materially reduced.

Hiccough.—Postoperative hiccough seems to be due most frequently to a reflex irritated by mechanical or chemical irritation in the stomach or lower portion of the esophagus or the region of the gallbladder or indeed to any lesion capable of producing irritation of the peritoneum in the subdiaphragmatic portion of the abdominal cavity. Accordingly hiccough is relatively common after operations on the gallbladder and stomach, especially in males. Lesions of the brain and spinal cord are apparently responsible in some cases.

Because postoperative hiccough may constitute the presenting symptom in such serious intra-abdominal complications as incipient peritonitis, intestinal obstruction and residual abscess formation, a careful examination of the patient should be made to detect such conditions if present. The cause being so variable and so frequently obscure both the prophylaxis and the active treatment of postoperative hiccough are unsatisfactory. Occasionally loosening or removal of drainage material, loosening of a too tight binder or mere movement of the patient in bed may suffice to relieve hiccough but in most cases other measures are required. These are (1) gastric lavage with or without Wangenstein suction, (2) inhalation of
